# Removing Unwanted Variation from High Dimensional Data with Negative Controls 

Johann A. Gagnon-Bartsch ${ }^{*} \quad$ Laurent Jacob ${ }^{\dagger} \quad$ Terence P. Speed ${ }^{* \ddagger}$

December 2, 2013

#### Abstract

High dimensional data suffer from unwanted variation, such as the batch effects common in microarray data. Unwanted variation complicates the analysis of high dimensional data, leading to high rates of false discoveries, high rates of missed discoveries, or both. In many cases the factors causing the unwanted variation are unknown and must be inferred from the data. In such cases, negative controls may be used to identify the unwanted variation and separate it from the wanted variation. We present a new method, RUV-4, to adjust for unwanted variation in high dimensional data with negative controls. RUV-4 may be used when the goal of the analysis is to determine which of the features are truly associated with a given factor of interest. One nice property of RUV-4 is that it is relatively insensitive to the number of unwanted factors included in the model; this makes estimating the number of factors less critical. We also present a novel method for estimating the features' variances that may be used even when a large number of unwanted factors are included in the model and the design matrix is full rank. We name this the "inverse method for estimating variances." By combining RUV-4 with the inverse method, it is no longer necessary to estimate the number of unwanted factors at all. Using both real and simulated data we compare the performance of RUV-4 with that of other adjustment methods such as SVA, LEAPP, ICE, and RUV-2. We find that RUV-4 and its variants perform as well or better than other methods.

## 1 Introduction

High dimensional data often suffer from unwanted variation. Microarray data, for example, frequently exhibit batch effects and many other forms of unwanted variation (Leek et al., 2010; Scherer, 2009; Stafford, 2008). This unwanted variation may be either technical or biological in nature, and the sources of this unwanted variation may range from RNA degradation during the time between sample extraction and preservation, to the amount of ozone in the air, to the natural day-to-day and hour-to-hour variation within a subject. For references, see Baggerly et al. (2008), Bakay et al. (2002), Ballard et al. (2007), Boedigheimer et al. (2008), Boelens et al. (2007), Fare et al. (2003), Huang et al. (2001), Lin et al. (2006), Ma et al. (2006), Schaupp et al. (2005), Thompson et al. (2007), Whitney et al. (2003); this list is hardly complete. Microarray data are not the only high dimensional data that suffer from unwanted variation. Functional Magnetic Resonance Imaging (fMRI) data are often corrupted by changes in the rate of blood flow, the level of blood oxygenation, and many other factors (Behzadi et al., 2007). NMR spectroscopic metabonomic data may be influenced by changes in sample volume or other factors (Craig et al., 2006; Ebbels et al., 2011) and other forms of metabolomic data are also afflicted (De Livera et al., 2012). Proteomics data suffer as well (Karpievitch et al., 2009).

Unwanted variation complicates the analysis of high dimensional data. Unwanted variation may lead to high rates of false discoveries, high rates of missed discoveries, or both. Consider an example in which a

[^0]researcher wishes to learn which features of the data are associated with a particular factor of interest. For example, a researcher may wish to use fMRI data to learn which regions of the brain are activated by a particular auditory stimulus. If there are unwanted factors (e.g. blood flow) that are correlated with the factor of interest (the auditory stimulus), this confounding of the stimulus with blood flow may lead to false discoveries. Conversely, if there are unwanted factors that are uncorrelated with the stimulus, the unwanted variation may simply obscure any true association between the stimulus and brain activity levels, and thus lead to missed discoveries.

The causes of unwanted variation are often partially or entirely unknown. In some cases, factors that cause unwanted variation are known (e.g. blood flow), but cannot be easily or precisely measured. In other cases, only proxies of the true unwanted factors may be known. For example, in a microarray study, "batch effects" may be created if samples in one batch are processed at a higher temperature than in another batch. A researcher may know that a batch effect exists, and even know which samples were processed in which batch, but not know the cause of the batch effect (temperature). The researcher may try to model the unwanted variation using a dummy variable for batch. However, the batch variable is only a proxy for temperature. If the temperature varied within batches as well as between batches, the batch variable may be a poor proxy. Of course, in many other cases, even proxy variables are unavailable, and the causes of unwanted variation are a complete mystery.

This complicates the removal of unwanted variation. If the factors causing the unwanted variation are unknown, or even just poorly measured, it becomes difficult to discern what variation may be attributed to the unwanted factors. It becomes correspondingly difficult to discern what variation may actually be attributed to the factor of interest. A researcher trying to remove unwanted variation may fail to remove all of the unwanted variation, may accidentally remove the variation of interest, or both.

In such situations, negative controls may play a critical role in identifying the unwanted variation. Negative controls are features (e.g. genes, voxels, etc.) that are known a priori to be truly unassociated with the factor of interest. For example, in the hypothetical fMRI study described above, a researcher may wish to regard voxels in the white matter or cerebrospinal fluid, or perhaps even the primary visual cortex (V1), to be negative controls. In gene expression studies it is often reasonable to regard housekeeping genes as negative controls. Negative controls can be used to identify unwanted variation. Since negative controls are assumed to be truly unassociated with the factor of interest, any observed variation in the negative controls can be assumed to be unwanted variation. This allows a researcher to infer the unwanted factors. The researcher may then use the inferred unwanted factors to separate wanted variation from unwanted variation. Specific algorithms that exploit negative controls in this way have been proposed by Lucas et al. (2006), Behzadi et al. (2007), Wu and Aryee (2010), and Gagnon-Bartsch and Speed (2012).

In this paper we will build on this work and present novel methods to remove unwanted variation from high dimensional data with negative controls. For concreteness, we will focus on microarray data, but we believe the methods of this paper should be widely applicable to many other types of high dimensional data. The structure of this paper is as follows. In what remains of the introduction we provide a brief summary of existing methods to remove unwanted variation and highlight the novel contributions of this paper. In Section 2 we present the datasets we will use to evaluate the performance of our methods. In Section 3 we present our methods. In Section 4 we evaluate the performance of our methods using simulated data, and in Section 5 we evaluate the performance of our methods on the real datasets of Section 2. Section 6 concludes.

Methods to adjust for unwanted variation can be divided into two broad categories. In the first category are methods that can be used quite generally, and provide a global adjustment. A global adjustment produces a modified (adjusted) dataset that is essentially identical to the original dataset but - hopefully - with the unwanted variation removed. An example of a global adjustment would be quantile normalization, which is commonly used in the preprocessing of microarray data. Quantile normalization is generally regarded as a self-contained step, and plays no role in the downstream analysis of the data. In the second category of adjustment methods are application specific methods. Application specific methods integrate the adjustment for unwanted variation directly into the main analysis of interest. For example, in a microarray differential expression study, batch effects may be handled by explicitly adding batch terms to a linear model. A modified (adjusted) dataset is not created in the process. Thus, this method is application specific in the sense that it
is only useful in the context of a differential expression analysis. It is not necessarily clear how - or whether - the method may be altered in order to adjust for unwanted variation in other types of analyses, such as classification or clustering analyses. For further discussion, see Gagnon-Bartsch and Speed (2012).

Much of the progress that has been made in removing unwanted variation from microarray data has been with application specific methods intended for use in differential expression analyses. In some of these methods it is assumed that the factors causing the unwanted variation are known. Combat is one such successful and well-known method; in particular Combat has been shown to work well with small datasets (Johnson et al., 2007). While Combat and other similar methods can be quite successful, their use is limited by the assumption that the unwanted factors are known. As discussed above, the unwanted factors are often only partially known, or entirely unknown.

Other methods presume the sources of the unwanted variation to be unknown. Most of these methods use linear regression models. In some methods the unwanted variation is handled by including extra terms for the unwanted factors in the design matrix. The unwanted factors are inferred from the data using some form of factor analysis. Methods using this approach have been proposed by Leek and Storey (2007, 2008) (SVA), Stegle et al. (2008, 2010), Sun et al. (2012) (LEAPP), Desai and Storey (2012), and Gagnon-Bartsch and Speed (2012) (RUV-2). In other methods the unwanted variation is handled by folding the unwanted variation into the error term, and allowing the covariance of the error term to have a complicated structure. Methods using this approach have been proposed by Kang et al. (2008a) (ICE) and Listgarten et al. (2010) (LMM-EH). Other, related methods of potential interest include Yu et al. (2005), Patterson et al. (2006), Price et al. (2006), Kang et al. (2008b), Friguet et al. (2009), Karpievitch et al. (2009), Blum et al. (2010), Kang et al. (2010), Mecham et al. (2010), and Chakraborty et al. (2012). Some of the first uses of factor analysis to adjust for unwanted variation can be found in Alter et al. (2000) and Nielsen et al. (2002), although in these examples there is no explicit linear model.

In this paper we will build primarily upon the work of Gagnon-Bartsch and Speed (2012). GagnonBartsch and Speed (2012) proposed a simple, two-step method (RUV-2) to adjust for unwanted variation using control genes. The method is application specific and meant for use in differential expression studies. The two steps of RUV-2 are: 1) perform factor analysis on the control genes to infer the unwanted factors, and 2) perform a simple linear regression of the observed expression levels on the factor of interest, including the inferred unwanted factors in the model as covariates.

The contributions of this paper are several. To begin, we present a new method, RUV-4. RUV-4 superficially resembles RUV-2. RUV-4 is intended for use in differential expression studies, uses control genes to identify unwanted factors, and includes the estimated unwanted factors as covariates in a regression model. However, the exact method by which the unwanted factors are estimated is different, and this difference has important statistical implications. The performance of RUV-2 is relatively sensitive to the number $K$ of unwanted factors that are included in the regression model. The performance of RUV-4 is much less sensitive to the choice of $K$. Compared to RUV-2, RUV-4 is also much less sensitive to violations of the control genes assumption, i.e. situations in which the designated "negative controls" are in fact truly associated with the factor of interest.

RUV-4 is also of theoretical interest. It is possible to view RUV-4 as a method in which unwanted factors are inferred from the data and then included in the design matrix of a regression model. In this way, RUV-4 is similar to RUV-2, SVA, LEAPP, and other related methods. However, we show that it is also possible to view RUV-4 as form of generalized least squares (GLS). In this way, RUV-4 is similar to ICE, LMM-EH, and other related methods. RUV-4 provides an interesting theoretical link between these two classes of methods. Perhaps more importantly, however, RUV-4 may also be viewed as an exercise in prediction, or function estimation. This view of RUV-4 is important for two reasons. Firstly, it allows for a deeper understanding of the assumptions of RUV-4, giving researchers more insight into when RUV-4 is likely to succeed, when it may fail, and why. Secondly, viewing RUV-4 as a prediction problem leads quickly and naturally to ideas for more advanced methods.

Another important contribution of this paper is a novel method for estimating variances, which we name the "inverse method." This method, which uses random "factors of interest," allows us to estimate gene-wise variances even when all available degrees of freedom have been used up adjusting for unwanted variation,
i.e. when $K$ is so large that the design matrix is full rank. By using the inverse method, we may simply set $K$ to be very large by default, and in most cases suffer no performance penalty. Thus, the inverse method eliminates any need to estimate the number of unwanted factors. Nonetheless, methods somewhat related to the inverse method may also be used to estimate the number of unwanted factors when such an estimate is needed. We present one such method that we have found to perform reasonably well in practice.

Additional contributions of this paper include 1) a "ridged" variant of RUV-4, useful in situations where only a small number of negative controls are available; 2 ) methods to empirically adjust estimates of variances, in order to achieve better control of the type I error rate; 3) a discussion on how negative controls might be discovered "empirically;" and 4) "projection plots," a novel diagnostic plot that allows a researcher to visualize the adjustment being made by RUV-2 or RUV-4, and assess whether this adjustment seems appropriate.

## 2 Data

In order to compare the relative performance of the methods discussed in this paper, we will want to apply the methods to a few real datasets. Following Gagnon-Bartsch and Speed (2012), we will investigate differential expression with respect to gender in the brain. The primary reason we investigate differential expression with respect to gender is because the answer is in some sense "known." It is sensible to assume a priori that most, if not all, of the genes differentially expressed with respect to gender in the brain will come from either the X or Y chromosomes. This observation provides us with some very straight-forward metrics with which we can compare the performance of various methods intended to find differentially expressed genes. We can, for example, simply take the 100 top-ranked genes (in terms of $p$-values) and count the number of these top-ranked genes that come from the X or Y chromosomes. With only a few minor caveats, we may regard the better method to be the one that finds more X/Y genes. See Gagnon-Bartsch and Speed (2012) for further discussion on the use of gene rankings as a quality metric, and discussion on quality metrics more generally.

We focus on the brain partly because the relatively complex biology of the brain makes finding differentially expressed genes more challenging, and partly because of the availability of several suitable datasets. Following Gagnon-Bartsch and Speed (2012), we will use data from three different studies: a "gender study" in which the original scientific goal was to find genes in the brain differentially expressed with respect to gender; an "Alzheimer's study" in which the original scientific goal was to find genes differentially expressed with respect to the severity of Alzheimer's disease, and the The Cancer Genome Atlas's (TCGA) glioblastoma multiforme study. To be clear, despite the fact that these studies were originally conducted with different scientific goals in mind, we will use each of these datasets in exactly the same way - to find genes differentially expressed with respect to gender. Further information on the gender and Alzheimer's studies can be found in Vawter et al. (2004) and Blalock et al. (2004), respectively.

In total we will examine 11 distinct datasets. We will examine two variants of the gender dataset. One has been fully preprocessed using RMA (Bolstad et al., 2003; Irizarry et al., 2003b,a). The other has not; the background correction and quantile normalization steps have been omitted. These two datasets are exactly those described in Gagnon-Bartsch and Speed (2012). The point of using data that has not been preprocessed is that it is much "noisier" than preprocessed data, and therefore more challenging. It is of interest to see how the various methods discussed in this paper handle this added challenge. Likewise, we examine both preprocessed and non-preprocessed versions of the Alzheimer's data. Again, these two datasets are exactly those described in Gagnon-Bartsch and Speed (2012).

The remaining seven datasets come from TCGA data. TCGA glioblastoma multiforme expression data is available from three different microarray platforms: the Affymetrix GeneChip Human Exon 1.0 ST array, the Affymetrix HT HG-U133A array, and the Agilent custom 244K array. Gagnon-Bartsch and Speed (2012) examined data from the two Affymetrix arrays. Here we examine datasets from all three arrays. Note however that the Affymetrix datasets that we examine in this paper are not identical to those in Gagnon-Bartsch and Speed (2012). TCGA has continued to assay additional samples, and the datasets we examine here have been "updated" to include many of the newer samples. Moreover, note that TCGA provides both raw
("Level 1") and preprocessed ("Level 3") data. Gagnon-Bartsch and Speed (2012) began with the raw data and performed the preprocessing themselves. Here however we simply downloaded TCGA's preprocessed datasets.

Three of the TCGA datasets that we examine are simply the three "full" datasets, i.e. one "full" dataset for each of the three platforms (Exon, U133A, and Agilent). We created a fourth TCGA dataset by combining data from all three platforms. Because the full datasets are all individually quite large, we included only a subset of the data from each of the three platforms. We included the first 100 arrays from the Exon dataset, the second 100 arrays from the U133A dataset, and the third 100 arrays from the Agilent dataset. The "combined" dataset therefore includes 300 samples, none of which are technical replicates. Only genes that are common to all three platforms are included in the "combined" dataset. The final three TCGA datasets are simply the three subsets of the "combined" dataset corresponding to each of the three platforms, i.e. the 100 Exon samples, the 100 U133A samples, and the 100 Agilent samples. Note that these "subset" datasets are subsets of the "full" datasets not only in the sense that they include only a subset of samples, but also in the sense that they include only a subset of the genes (specifically, those common to all the platforms). The point of examining these three "subset" datasets individually is so that we have a valid basis for comparison when we discuss the advantages and disadvantages of combining data from different platforms.

In Table 1 we report the number of samples $m$, the number of genes $n$, and the number of available control genes $n_{c}$ in each of the 11 datasets. The control genes we use are the housekeeping genes discovered by Eisenberg and Levanon (2003). This is the same set of housekeeping genes used by Gagnon-Bartsch and Speed (2012). Unlike Gagnon-Bartsch and Speed (2012) however, we do not discuss the use of spike-in controls in this paper.

|  | $m$ (\# of arrays) | $n$ (\# of genes) | $n_{c}$ (\# of control genes) |
| :--- | ---: | ---: | ---: |
| Gender (preprocessed) | 84 | 12600 | 799 |
| Gender (non-preprocessed) | 84 | 12600 | 799 |
| Alzheimer's (preprocessed) | 31 | 22283 | 1112 |
| Alzheimer's (non-preprocessed) | 31 | 22283 | 1112 |
| TCGA - Exon (Full) | 420 | 18632 | 518 |
| TCGA - U133A (Full) | 490 | 12042 | 520 |
| TCGA - Agilent (Full) | 466 | 17472 | 521 |
| TCGA - Combined | 300 | 11750 | 509 |
| TCGA - Exon (Subset) | 100 | 11750 | 509 |
| TCGA - U133A (Subset) | 100 | 11750 | 509 |
| TCGA - Agilent (Subset) | 100 | 11750 | 509 |

Table 1: The number of arrays, genes, and control genes in each dataset.

## 3 Methods

In this section we formally present the methods of this paper. In Section 3.1 we present a model and some notation. In Section 3.2 we review RUV-2 (Gagnon-Bartsch and Speed, 2012) and discuss its relationship to IVLS. In Section 3.3 we present RUV-4, one of the main contributions of this paper. We then compare RUV-4 to RUV-2 in Section 3.4. In Section 3.5 we investigate the basic statistical properties of RUV-4, and in Section 3.6 we consider additional statistical properties of RUV-4 that are particularly relevant to the use of RUV-4 with real data. In Section 3.7 we present the inverse method for estimating variances, a second important contribution of this paper. In Section 3.8 we introduce the functional approach. This section provides an alternative framework by which to understand the methods of this paper, and, just as importantly, suggests directions for future research. In Section 3.9 we present a few variations and extensions of the main methods of this paper.

### 3.1 Background and Model

First we present the model. Then we define some additional notation. Finally, we provide a brief general discussion of the statistical challenges we face when fitting the model.

### 3.1.1 The Model

Assume we have $m$ arrays each with $n$ genes (or probes or probesets). Let $y_{i j}$ denote the observed log expression level of the $j^{\text {th }}$ gene on the $i^{\text {th }}$ array, and let $Y$ denote the $m \times n$ matrix $\left(y_{i j}\right)$. We model $Y$ as:

$$
\begin{equation*}
Y_{m \times n}=X_{m \times p} \beta_{p \times n}+Z_{m \times q} \gamma_{q \times n}+W_{m \times k} \alpha_{k \times n}+\epsilon_{m \times n} \tag{1}
\end{equation*}
$$

where

$$
\begin{align*}
\operatorname{Rank}[(X|Z| W)] & =p+q+k<m  \tag{2}\\
\epsilon_{i j} & \sim N\left(0, \sigma_{j}^{2}\right)  \tag{3}\\
\epsilon_{i j} & \Perp \epsilon_{i^{\prime} j^{\prime}} \text { if }(i, j) \neq\left(i^{\prime}, j^{\prime}\right) \tag{4}
\end{align*}
$$

Here, $X$ is an observed matrix whose columns are the factors of interest (e.g. disease state, treatment / control), $Z$ is a matrix whose columns are observed covariates (e.g. batch, ethnicity), and $W$ is a matrix whose columns are unobserved covariates (e.g. sample quality). Note that $k$ is unobserved. The matrices $\beta$, $\gamma$, and $\alpha$ are all unobserved coefficients that determine the influence of a particular factor on a particular gene. We regard $X, Z, W, \beta, \gamma$, and $\sigma_{j}$ to be fixed. As for $\alpha$, in some sections we will regard it as fixed; in other sections we will regard it to be random. We begin by assuming it is fixed. When we do regard $\alpha$ as random we assume:

$$
\begin{array}{rll}
\alpha & \Perp & \epsilon \\
\alpha_{i j} & \Perp & \alpha_{i^{\prime} j^{\prime}} \text { if }(i, j) \neq\left(i^{\prime}, j^{\prime}\right) \tag{6}
\end{array}
$$

The $Z \gamma$ term is optional; a researcher may not be aware of any observed covariates, or may wish to treat observed covariates as if they were unobserved. Unless we specifically state otherwise, we will assume for simplicity that there are no observed covariates, and only one factor of interest. The model simplifies to

$$
\begin{equation*}
Y_{m \times n}=X_{m \times 1} \beta_{1 \times n}+W_{m \times k} \alpha_{k \times n}+\epsilon_{m \times n} \tag{7}
\end{equation*}
$$

### 3.1.2 Additional Notation

- Let $\sigma^{2}$ denote the $n$-dimensional vector of gene variances $\left(\sigma_{j}^{2}\right)$.
- Let $n_{c}$ denote the number of control genes.
- Let $Y_{c}, \alpha_{c}, \beta_{c}$, and $\epsilon_{c}$ be reduced versions of $Y, \alpha, \beta$, and $\epsilon$ that only contain the columns of the negative control genes. Thus $Y_{c}$ is an $m \times n_{c}$ matrix, $\alpha_{c}$ is $k \times n_{c}$, etc. Recall that negative control genes are genes that we assume are uninfluenced by the factor of interest. Thus we assume $\beta_{c}=0$. We refer to this as the "control gene assumption."
- Let $j_{c}$ index control genes and $j_{\bar{c}}$ index non-control genes.
- If $A$ is a matrix, denote the $i^{\text {th }}$ row of of $A$ by $A_{i \star}$ and the $j^{\text {th }}$ column of $A$ by $A_{\star j}$.
- If $A$ is a matrix with a single column, let $A_{i} \equiv A_{i 1}$. If $A$ is a matrix with a single row, let $A_{j} \equiv A_{1 j}$.
- Denote the range (column space) of a matrix $A$ by $\mathfrak{R}(A)$.
- Denote the projection operator of a matrix $A$ by $P_{A}$; i.e. $P_{A} \equiv A\left(A^{\prime} A\right)^{-1} A^{\prime}$ projects onto $\mathfrak{R}(A)$.
- Denote the residual operator of a matrix $A$ by $R_{A}$; i.e. $R_{A} \equiv I-A\left(A^{\prime} A\right)^{-1} A^{\prime}$ projects onto the orthogonal complement of $\mathfrak{R}(A)$.
- Denote the particularly important quantity $R_{X} W$ by $W_{0}$.
- If $A$ is some matrix with $N$ rows and rank $M<N$, let $A_{\perp}$ denote some (possibly arbitrary) rank $N-M$ matrix whose columns are unit length, mutually orthogonal, and such that $A^{\prime} A_{\perp}=0$.
- Denote the partial regression coefficient of $A$ on $B$ as $b_{A B}$ and the partial regression coefficient of $A$ on $B$ adjusted for $C$ as $b_{A B . C}$. Let $\beta_{A B}$ and $\beta_{A B . C}$ denote the associated parameters. Alternatively, readers may simply choose to regard the following as definitions:

$$
\begin{align*}
b_{Y X} & \equiv\left(X^{\prime} X\right)^{-1} X^{\prime} Y  \tag{8}\\
b_{Y_{c} X} & \equiv\left(X^{\prime} X\right)^{-1} X^{\prime} Y_{c}  \tag{9}\\
b_{W X} & \equiv\left(X^{\prime} X\right)^{-1} X^{\prime} W  \tag{10}\\
b_{Y_{c} X \cdot W} & \equiv\left(X^{\prime} R_{W} X\right)^{-1} X^{\prime} R_{W} Y_{c}  \tag{11}\\
b_{Y_{c} W \cdot X} & \equiv\left(W^{\prime} R_{X} W\right)^{-1} W^{\prime} R_{X} Y_{c}  \tag{12}\\
\beta_{Y_{c} X . W} & \equiv \beta_{c}  \tag{13}\\
\beta_{Y_{c} W \cdot X} & \equiv \alpha_{c} \tag{14}
\end{align*}
$$

Note: We will assume throughout this paper without loss of generality that the columns of $W_{0}$ are mutually orthogonal and have unit length, and that $\|X\|=1$ as well.

### 3.1.3 Statistical Challenges

Our model (7) closely resembles a standard linear regression model. The difference is that in our model $W$ is unobserved. A natural strategy to fit our model would therefore be to find some way to estimate $W$ and then proceed with standard regression. The difficulty with this approach is that $W$ is not identifiable without additional assumptions.

Let $A$ be any invertible $k \times k$ matrix. Then

$$
\begin{equation*}
(W A)\left(A^{-1} \alpha\right)=W \alpha \tag{15}
\end{equation*}
$$

so neither $W$ nor $\alpha$ are identifiable. However, this particular form of unidentifiability is not a problem. Our ultimate goal is to estimate $\beta$. For this, knowledge of the column-space of $W$ will suffice. To see this, note that knowledge of $\mathfrak{R}(W)$ would allow us to compute $R_{W}$, the residual operator of $W$. We could therefore calculate $\left(X^{\prime} R_{W} X\right)^{-1} X^{\prime} R_{W}$, the OLS estimate of $\beta$.

The real problem is that even $\mathfrak{R}(W)$ is unidentifiable. To illustrate the unidentifiability, let $a$ be an arbitrary $1 \times k$ row-matrix. Then

$$
\begin{equation*}
X(\beta+a \alpha)+(W-X a) \alpha=X \beta+W \alpha \tag{16}
\end{equation*}
$$

In words, since we don't know the correlation of $X$ and $W$, we are unable to separate $\beta$ from $\alpha$. This is the fundamental problem that needs solving. Our solution is to use control genes. As we will see, the assumption that $\beta_{c}=0$, along with a few other technical assumptions, is enough to make $\mathfrak{R}(W)$, and thus $\beta$, identifiable.

### 3.2 The Two-Step Method (RUV-2)

First we present the method. Then we provide a brief discussion.

### 3.2.1 The Method

Consider only the expression values for the negative control genes. By (7),

$$
\begin{equation*}
Y_{c}=X \beta_{c}+W \alpha_{c}+\epsilon_{c} . \tag{17}
\end{equation*}
$$

The "control gene assumption" however is that $\beta_{c}=0$, so (17) becomes

$$
\begin{equation*}
Y_{c}=W \alpha_{c}+\epsilon_{c} \tag{18}
\end{equation*}
$$

This is a typical model in factor analysis, and many methods exist to estimate $W$ (e.g. SVD). The two-step method therefore is to

- Step 1: Estimate $W$ by factor analysis on $Y_{c}$.
- Step 2: Estimate $\beta$ by regressing $Y$ on $X$ and the estimate of $W$.

More explicitly, we may denote the estimate of $W$ as $\hat{W}^{(R U V-2)}$ and define

$$
\begin{equation*}
\hat{\beta}^{(\mathrm{RUV}-2)} \equiv\left(X^{\prime} R_{\hat{W}^{(\mathrm{RUV}-2)}} X\right)^{-1} X^{\prime} R_{\hat{W}^{(\mathrm{RUV}-2)}} Y \tag{19}
\end{equation*}
$$

In the future, we will drop the RUV-2 superscript when it is clear from context.

### 3.2.2 Relationship to IVLS and Further Discussion

RUV-2 is discussed in depth by Gagnon-Bartsch and Speed (2012). In this paragraph we merely summarize some important points of this work. The first is that no matter what factor analysis method is used, $W$ can only be estimated if $\operatorname{rank}\left(\alpha_{c}\right)=k$. This means that in addition to requiring that the control genes be unassociated with the factor of interest, we must also require that they be associated with the unwanted factors. Choosing an appropriate set of control genes is essential to the success of RUV-2. A second point is that we must estimate $k$. This can be very difficult. Again, see Gagnon-Bartsch and Speed (2012) for more on this matter.

One point not discussed in Gagnon-Bartsch and Speed (2012) is the relationship of RUV-2 to instrumental variables least squares (IVLS). Some readers may find RUV-2 reminiscent of IVLS. (Readers unfamiliar with IVLS may wish to consult Freedman (2009).) Indeed, there are some similarities. Let $V$ be a full rank $m \times r$ matrix of instruments such that $m>r \geq p$, such that $V^{\prime} W \approx 0$, and such that $V^{\prime} X$ is full rank. An IVLS estimator of $\beta$ would be $\left[X^{\prime} V\left(V^{\prime} V\right)^{-1} V^{\prime} X\right]^{-1} X^{\prime} V\left(V^{\prime} V\right)^{-1} V^{\prime} Y$. Alternatively, we may write this IVLS estimator as $\left(X^{\prime} P_{V} X\right)^{-1} X^{\prime} P_{V} Y$. Compare the IVLS estimator to the RUV-2 estimator $\left(X^{\prime} R_{\hat{W}} X\right)^{-1} X^{\prime} R_{\hat{W}} Y$. With both the IVLS estimator and the RUV-2 estimator, we "avoid" the unwanted variation by projecting the data into a "safe" subspace that is (approximately) orthogonal to $\mathfrak{R}(W)$. In the case of IVLS the "safe" subspace is $\mathfrak{R}(V)$. This subspace is orthogonal to $\mathfrak{R}(W)$ by assumption. In practice, the assumption that $\mathfrak{R}(V)$ is orthogonal to $\mathfrak{R}(W)$ usually derives from the assumption that $W$ and $V$ are stochastically independent. In the case of RUV-2 the "safe" subspace is $\mathfrak{R}\left(\hat{W}_{\perp}\right)$. This subspace is orthogonal to $\mathfrak{R}(W)$ if $\mathfrak{R}(W) \subseteq \mathfrak{R}(\hat{W})$. In practice, the assumption that $\mathfrak{R}(W) \subseteq \mathfrak{R}(\hat{W})$ derives from the assumptions that $\operatorname{rank}\left(\alpha_{c}\right)=k$, that $\hat{k} \geq k$, and that the factor analysis "works."

We might choose to view IVLS and RUV-2 as complementary. With IVLS we identify a "safe" subspace using instruments. Instruments are variables that we assume lie within the "safe" subspace. With RUV-2 we identify a "safe" subspace using negative controls. Negative controls are variables that we assume lie within the "dangerous" subspace that is the orthogonal complement of the "safe" subspace. With both IVLS and RUV-2 there is a caveat. The caveat is that $X$ must not be orthogonal to the "safe" subspace. In the case of IVLS, this means that $V$ must be reasonably correlated with $X$; we want to avoid weak instruments. In the case of RUV-2, this means that $X$ must lie outside $\mathfrak{R}(\hat{W})$; the control genes must not be influenced by $X$.

### 3.3 The Four-Step Method (RUV-4)

We now present a new method to estimate $\beta$. As we did with RUV-2, we first present the method and then provide a brief discussion.

### 3.3.1 The Method

We estimate $\beta$ in four steps.

## - Step 1: Fit and Remove $X$

Multiply both sides of (7) by $R_{X}$ to obtain

$$
\begin{align*}
R_{X} Y & =R_{X} X \beta+R_{X} W \alpha+R_{X} \epsilon  \tag{20}\\
& =W_{0} \alpha+R_{X} \epsilon \tag{21}
\end{align*}
$$

## - Step 2: Factor Analysis

Use some variant of factor analysis to produce an estimate $\widehat{W_{0} \alpha}$ of $W_{0} \alpha$. In addition, define individual estimates $\hat{W}_{0}$ and $\hat{\alpha}$ such that $\hat{W}_{0} \hat{\alpha}=\widehat{W_{0} \alpha}$. Although we need not commit to a specific method of factor analysis, we impose two requirements:

$$
\begin{equation*}
P_{X} \hat{W}_{0}=0 \tag{22}
\end{equation*}
$$

and

$$
\begin{equation*}
\hat{\alpha}=\left(\hat{W}_{0}^{\prime} \hat{W}_{0}\right)^{-1} \hat{W}_{0}^{\prime} Y \tag{23}
\end{equation*}
$$

Note that $W_{0}$ and $\alpha$ are not identifiable, so the factorization of $\widehat{W_{0} \alpha}$ into $\hat{W}_{0}$ and $\hat{\alpha}$ will be somewhat arbitrary; this turns out not to matter.

- Step 3: Estimate W

We begin with the observation that

$$
\begin{align*}
W & =W-X\left(X^{\prime} X\right)^{-1} X^{\prime} W+X\left(X^{\prime} X\right)^{-1} X^{\prime} W \\
& =\left(I-X\left(X^{\prime} X\right)^{-1} X^{\prime}\right) W+X\left[\left(X^{\prime} X\right)^{-1} X^{\prime} W\right] \\
& =W_{0}+X b_{W X} \tag{24}
\end{align*}
$$

We know $X$ and we have an estimate of $W_{0}$. We therefore would like to estimate $b_{W X}$. To do so we make use of the identity

$$
\begin{equation*}
b_{Y_{c} X}=b_{Y_{c} X . W}+b_{W X} b_{Y_{c} W \cdot X} \tag{25}
\end{equation*}
$$

Assuming $\left(b_{Y_{c} W \cdot X} b_{Y_{c} W \cdot X}^{\prime}\right)^{-1}$ exists, solving for $b_{W X}$ yields

$$
\begin{equation*}
b_{W X}=\left(b_{Y_{c} X}-b_{Y_{c} X \cdot W}\right) b_{Y_{c} W \cdot X}^{\prime}\left(b_{Y_{c} W \cdot X} b_{Y_{c} W \cdot X}^{\prime}\right)^{-1} \tag{26}
\end{equation*}
$$

Note that

$$
\begin{equation*}
b_{Y_{c} X . W} \approx \beta_{Y_{c} X . W}=\beta_{c}=0 \tag{27}
\end{equation*}
$$

and

$$
\begin{equation*}
b_{Y_{c} W \cdot X} \approx \beta_{Y_{c} W \cdot X}=\alpha_{c} \approx \hat{\alpha}_{c} \tag{28}
\end{equation*}
$$

SO

$$
\begin{equation*}
b_{W X} \approx b_{Y_{c} X} \hat{\alpha}_{c}^{\prime}\left(\hat{\alpha}_{c} \hat{\alpha}_{c}^{\prime}\right)^{-1} \tag{29}
\end{equation*}
$$

We therefore define our estimate of $W$ as

$$
\begin{equation*}
\hat{W} \equiv \hat{W}_{0}+X b_{Y_{c} X} \hat{\alpha}_{c}^{\prime}\left(\hat{\alpha}_{c} \hat{\alpha}_{c}^{\prime}\right)^{-1} \tag{30}
\end{equation*}
$$

## - Step 4: Regress $Y$ onto $X$ and $\hat{W}$ to estimate $\beta$

Just as in the two-step method, we plug in our estimate of $W$ as a covariate in a regression model. More explicitly, we may denote $\hat{W}$ as $\hat{W}^{(\mathrm{RUV}-4)}$ and define

$$
\begin{equation*}
\hat{\beta}^{(\mathrm{RUV}-4)} \equiv\left(X^{\prime} R_{\hat{W}^{(\mathrm{RUV}-4)}} X\right)^{-1} X^{\prime} R_{\hat{W}^{(\mathrm{RUV}-4)}} Y \tag{31}
\end{equation*}
$$

Again, we will drop the superscript when it is clear from context.

### 3.3.2 Discussion

RUV-4 may be roughly regarded as a hybrid between RUV-2 and SVA (Leek and Storey, 2007, 2008). Recall that a central problem when using factor analysis to discover unwanted factors is that the factor analysis might also pick up signal from the biological factor of interest. RUV-2 addressed this problem by limiting the factor analysis to negative control genes. Leek and Storey proposed a different solution: first remove the signal of interest by projecting the data onto the orthogonal complement of $\mathfrak{R}(X)$, and only then do the factor analysis. This effectively solves the problem of picking up the factor of interest in the factor analysis, and we borrow the technique in steps 1 and 2 of RUV-4.

However, this technique introduces a problem of its own. A factor analysis on $R_{X} Y$ will not accurately estimate the unwanted factors $W$. Instead, it will estimate $W_{0}$. Therefore, we need to recover the bit of $W$ that was projected away in step 1 . This is complicated by the unidentifiability of $\mathfrak{R}(W)$ highlighted in (16). We address this problem by borrowing the main idea of RUV-2 - that negative control genes can be used to make $\mathfrak{R}(W)$ identifiable.

Step 3 of RUV-4 is where we attempt to recover the component of $W$ lost in step 1 . Step 3 is the most important and complicated step, so we clarify a few points. The control gene assumption enters in (27), when we assume $b_{Y_{c} X . W} \approx 0$. The exact interpretation of this assumption is a bit subtle. Recall that $b_{Y_{c} X . W}$ is the partial regression coefficient of $Y_{c}$ on $X$ adjusted for $W$. In other words, it is the OLS estimate of $\beta_{c}$ that we would get in a regression of $Y_{c}$ on $X$ and $W$, if in fact we had the true $W$ available to us. Since we assume $\beta_{c}=0$, and since $b_{Y_{c} X . W}$ is the hypothetical OLS estimate of $\beta_{c}$, we conclude $b_{Y_{c} X . W} \approx 0$. To be even more precise, note that

$$
\begin{align*}
b_{Y_{c} X . W} & =\left(X^{\prime} R_{W} X\right)^{-1} X^{\prime} R_{W} Y_{c}  \tag{32}\\
& =\left(X^{\prime} R_{W} X\right)^{-1} X^{\prime} R_{W}\left(X \beta_{c}+W \alpha_{c}+\epsilon_{c}\right)  \tag{33}\\
& =\beta_{c}+\left(X^{\prime} R_{W} X\right)^{-1} X^{\prime} R_{W} \epsilon_{c}  \tag{34}\\
& =\left(X^{\prime} R_{W} X\right)^{-1} X^{\prime} R_{W} \epsilon_{c} \tag{35}
\end{align*}
$$

and that $\mathbb{E}\left[\left(X^{\prime} R_{W} X\right)^{-1} X^{\prime} R_{W} \epsilon_{c}\right]=0$.
The exact interpretation of (28) is subtle as well. We assume that $b_{Y_{c} W \cdot X} \approx \alpha_{c}$, that $\hat{\alpha}_{c} \approx \alpha_{c}$, and thus that $b_{Y_{c} W . X} \approx \hat{\alpha}_{c}$. The first of these assumptions is analogous to our assumption that $b_{Y_{c} X . W} \approx \beta_{c}$. The second assumption is simply that our estimate of $\alpha_{c}$ from step 2 (factor analysis) is in fact a good estimate of $\alpha_{c}$. The composite assumption that $b_{Y_{c} W \cdot X} \approx \hat{\alpha}_{c}$ is therefore an assumption that two different estimates of $\alpha_{c}$ - one hypothetical, and one obtainable - are approximately equal to one another. A different way to view this assumption is as follows: $b_{Y_{c} X . W}=\left(W_{0}^{\prime} W_{0}^{\prime}\right)^{-1} W_{0}^{\prime} Y_{c}$ and $\hat{\alpha}_{c}=\left(\hat{W}_{0}^{\prime} \hat{W}_{0}\right)^{-1} \hat{W}_{0}^{\prime} Y_{c}$. Therefore, if $\hat{W}_{0} \approx W_{0}, b_{Y_{c} X . W} \approx \hat{\alpha}_{c}$. Indeed, if $\hat{W}_{0}$ is a particularly good estimate of $W_{0}$, it may turn out that $b_{Y_{c} X . W}$ and $\hat{\alpha}_{c}$ are closer to one another than either is to $\alpha_{c}$. In fact, since $\hat{W}_{0}$ is in general a better estimate of $W_{0}$ than $\hat{\alpha}$ is of $\alpha$ (a consequence of the fact that $n \gg m$ ), it may often be the case in practice that $b_{Y_{c} X . W}$ and $\hat{\alpha}_{c}$ are closer to one another than either is to $\alpha_{c}$. Finally, a minor technical point: A careful reader might object that the unidentifiability of $W$ and $\alpha$ expressed in (15) implies that $\hat{W}_{0}$ and $W_{0}$ are not necessarily approximately equal to one another, and likewise for $\hat{\alpha}$ and $\alpha$. This is true - recall that the factorization of $\widehat{W_{0} \alpha}$ into $\hat{W}_{0}$ and $\hat{\alpha}$ is arbitrary. However, it can be shown that $\hat{\beta}^{(R U V-4)}$ is independent of the choice of factorization. See Section (A.1) in the SM.

A reformulation of $\hat{\beta}^{(\mathrm{RUV}-4)}$ that will prove useful later is:

$$
\begin{equation*}
\hat{\beta}^{(\mathrm{RUV}-4)}=\left(X^{\prime} X\right)^{-1} X^{\prime}(Y-\hat{W} \hat{\alpha}) \tag{36}
\end{equation*}
$$

To see that this is true, note that we have defined $\hat{\beta}^{(R U V-4)}$ in (31) as the OLS coefficient of $X$ in a regression of $Y$ on $X$ and $\hat{W}$. Note further that as a consequence of (22) and (23), $\hat{\alpha}$ is the OLS coefficient of $\hat{W}$ in a regression of $Y$ on $X$ and $\hat{W}$, and that therefore $\left(X^{\prime} X\right)^{-1} X^{\prime}(Y-\hat{W} \hat{\alpha})$ is also the OLS coefficient of $X$ in a regression of $Y$ on $X$ and $\hat{W}$. Finally, note that (36) can itself be reformulated as

$$
\begin{equation*}
\hat{\beta}^{(\mathrm{RUV}-4)}=b_{Y X}-\hat{b}_{W X} \hat{\alpha} \tag{37}
\end{equation*}
$$

where $\hat{b}_{W X} \equiv b_{Y_{c} X} \hat{\alpha}_{c}^{\prime}\left(\hat{\alpha}_{c} \hat{\alpha}_{c}^{\prime}\right)^{-1}$.
Finally, some additional notation. Let $\hat{k}$ denote an estimator of $k$. In Section 3.6.6 we will explicitly define $\hat{k}$; until then we may think of $\hat{k}$ as representing some arbitrary estimator. Let $\hat{W}_{0}^{(K)}$ denote the estimate of $W_{0}$ that we would get in Step 2 if we instructed our factor analysis routine to produce an estimate of $W$ that was of dimension $m \times K$. Similarly denote $\hat{\alpha}^{(K)}, \hat{b}_{W X}^{(K)}, \hat{W}^{(K)}$, etc. as the estimates of $\alpha, b_{W X}$, $W$, etc. that we would subsequently produce if we were to use $\hat{W}_{0}^{(K)}$ as our estimate of $W_{0}$. Note that there are three " k " $\mathrm{s}: k$ is the true parameter in the model; $\hat{k}$ is an estimate of $k$; and $K$ may be viewed either as a parameter in an algorithm, or simply as an index variable.

### 3.4 Comparison of RUV-2 and RUV-4

In both RUV-2 and RUV-4, we estimate $\hat{\beta}$ by first estimating $W$, and then regressing $Y$ on $X$ and $\hat{W}$. The difference between the methods is only in how we estimate $W$. In both methods, however, we use factor analysis to estimate $W$, making special use of control genes to make $\mathfrak{R}(W)$ identifiable. It is therefore natural to ask whether there are any substantive differences between the methods. Indeed there are, and in this section we attempt to develop some intuition for these differences using a few simple examples and illustrations.

Consider a very simple example in which $m=2$ and $k=1$. Note that in this specific example, $W_{0}=X_{\perp}$. Note in particular that we do not need any factor analysis to "discover" $W_{0}$. Step 2 of RUV-4 is therefore irrelevant in this example, but this does not seriously detract from the intuition we develop in the discussion that follows.

Now, note that because $m=2$, for any gene $j$ the vector of expression levels across samples (i.e. $Y_{\star j}$ ) is a two-dimensional vector and can be plotted as a point on a standard coordinate plane. $X$ and $W_{0}$ form a natural set of basis vectors against which we can plot $Y_{\star j}$. Such plots of $Y$ against $X$ and $W_{0}$ are very helpful for developing an intuitive understanding of RUV-4; as we will see later, they are also a very useful diagnostic tool.

Figure 1 decomposes such a plot for a single $Y_{\star j}$. A few simplifications are made for visual clarity. We suppress the subscripts on $Y_{\star j}, \beta_{j}$, etc. Far more importantly, we do not distinguish between $W$ and $\hat{W}$ (or between $b_{W X}$ and $\left.\hat{b}_{W X}\right)$. Although the distinction between $W$ and $\hat{W}$ is an important one, including both $W$ and $\hat{W}$ (and $b_{W X}$ and $\hat{b}_{W X}$ ) in the figure introduces too much clutter. We leave the distinction to the reader's imagination.

In Figure 1 we see that $Y_{\star j}$ is the vector sum of $X \beta_{j}, W \alpha_{j}$, and $\epsilon_{\star j}$. We decompose $Y_{\star j}$ into a horizontal component and a vertical component. The magnitude of the horizontal ( $W_{0}$ ) component gives us an estimate of how much of the unwanted factor is present; i.e. it is our $\hat{\alpha}_{j}$. This estimate is unbiased, and accurate up to the error introduced by the horizontal component of $\epsilon_{\star j}$. The vertical component of $Y_{\star j}$ (i.e. $b_{Y_{\star j} X}$ ) may be regarded as the "observed $X$-signal." The magnitude of the "observed $X$-signal" is the sum of three terms - the "true $X$-signal" $\beta_{j}$, the magnitude of the vertical component of $W \alpha_{j}$, and the magnitude of the vertical component of $\epsilon_{\star j}$. There is not much we can do about the vertical component of $\epsilon_{\star j}$, but we can try to adjust for the vertical component of $W \alpha_{j}$. We can estimate the magnitude of the vertical component of $W \alpha_{j}$ by $\hat{b}_{W X} \hat{\alpha}_{j}$. We can thus subtract $\hat{b}_{W X} \hat{\alpha}_{j}$ from the "observed $X$-signal" $b_{Y_{\star j} X}$ to produce our estimate $\hat{\beta}_{j}$ of $\beta_{j}$. Note that in this way, we have just graphically re-derived formula (37) - however, we have left out the important detail of where $\hat{b}_{W X}$ comes from!

Figure 2 shows where $\hat{b}_{W X}$ comes from. Instead of plotting $Y_{\star j}$ for a single gene $j$, we plot all $n=1000$ genes. Control genes are plotted as green. Genes for which $\beta_{j} \neq 0$ are plotted as purple. All other genes

Figure 1: A graphical depiction of RUV-4. See main text for commentary.
(i.e. genes for which $\beta_{j}=0$ but which are not specifically designated as control genes) are plotted as gray. $W$ is plotted as black. $\hat{W}$ is plotted as orange. For one arbitrary example gene (plotted as solid purple) we show that $\hat{\beta}_{j}$ is the vertical distance from $Y_{\star j}$ to the dotted orange line spanned by $\hat{W}$.

Now, $\hat{b}_{W X}$ is simply the slope of the dotted orange line. Estimating $b_{W X}$ (and thus $W$ ) therefore amounts to choosing the slope of this "baseline" from which we measure $\hat{\beta}_{j}$. The RUV-4 strategy for choosing this slope is to draw the regression line (without an intercept) through the control genes (green). That is why $\hat{b}_{W X}=b_{Y_{c} X} \hat{\alpha}_{c}^{\prime}\left(\hat{\alpha}_{c} \hat{\alpha}_{c}^{\prime}\right)^{-1}$.

We are now in a position to compare RUV-4 with RUV-2. Figure 3A compares the RUV-4 and RUV-2 estimators using the same example data as in Figure 2. To reduce clutter, we have removed the vector representation of $\hat{W}^{(\text {RUV -4) }}$, leaving only the orange dotted line to show its span. The brown dotted line is the span of $\hat{W}^{(\mathrm{RUV}-2)}$. Just as $\hat{\beta}_{j}^{(\mathrm{RUV}-4)}$ is the vertical distance from $Y_{\star j}$ to the orange dotted line, $\hat{\beta}_{j}^{(\mathrm{RUV}-2)}$ is the vertical distance from $Y_{\star j}$ to the brown dotted line. The difference between RUV-4 and RUV-2 is essentially the difference between these two lines. We have seen that the orange dotted line is the regression line through the control genes. To see where the brown dotted line comes from, recall that in RUV-2 we estimate $W$ by taking the first $k$ eigenvectors of $Y_{c} Y_{c}^{\prime}$. Since $k=1$ in this example, $\hat{W}^{(\mathrm{RUV}-2)}$ is simply the principal eigenvector of $Y_{c} Y_{c}^{\prime}$. To assist in visualizing this, we have included in Figure 3A a green ellipse that "summarizes" the structure of $Y_{c} Y_{c}^{\prime}$. The major and minor axes of this ellipse are aligned with the

Figure 2: A graphical depiction of the estimation of $b_{W X}$. See main text for commentary. The simulated data were generated as follows: $X=(0,1)^{\prime} ; W=(1,0.5)^{\prime} ; \alpha_{j} \sim \mathrm{~N}(0,1) ; \epsilon_{i j} \sim \mathrm{~N}\left(0, \frac{1}{16}\right) ; \beta_{j} \sim \mathrm{~N}\left(0, \frac{9}{4}\right)$ for $1 \leq j \leq 50 ; \beta_{j}=0$ for $51 \leq j \leq 1000$.
first and second eigenvectors of $Y_{c} Y_{c}^{\prime}$, and the lengths of the axes are proportional to the square roots of the associated eigenvalues. As we see in the plot, the brown dotted line goes directly along the major axis of this ellipse. Roughly speaking then, we may summarize the difference between RUV-2 and RUV-4 in the terminology of Freedman et al. (2007) as this: where RUV-2 uses the SD line, RUV-4 uses the regression line. ${ }^{1}$

In Figure 3A, there is little difference between $\hat{\beta}_{j}^{(\mathrm{RUV}-2)}$ and $\hat{\beta}_{j}^{(\mathrm{RUV}-4)}$. Figure 3B, however, provides an example in which the difference between $\hat{\beta}_{j}^{(\operatorname{RUV}-2)}$ and $\hat{\beta}_{j}^{(\mathrm{RUV}-4)}$ is quite substantial. The reason for the difference between the two estimators in Figure 3B is that the unwanted variation is less pronounced. While some unwanted variation from $W \alpha$ is clearly present, most of the scatter in the plot is purely random, i.e. comes from $\epsilon$. Graphically, this can also be seen in the fact that the green ellipse is much more circular.

RUV-2 and RUV-4 are clearly different, but which is better? As we can see in Figure 3B, RUV-2 seems to do a better job at accurately estimating $W$. On the other hand, it also appears that RUV-4 provides what our intuition might suggest to be the better estimate of $\beta_{j}$. This leads to a curious conclusion - that

[^1]

Figure 3: A comparison of RUV-4 and RUV-2. See main text for commentary. The simulated data in B were generated as follows: $X=(0,1)^{\prime} ; W=(1,1)^{\prime} ; \alpha_{j} \sim \mathrm{~N}\left(0, \frac{9}{64}\right) ; \epsilon_{i j} \sim \mathrm{~N}\left(0, \frac{1}{4}\right) ; \beta_{j} \sim \mathrm{~N}\left(0, \frac{9}{4}\right)$ for $1 \leq j \leq 50$; $\beta_{j}=0$ for $51 \leq j \leq 1000$.
to get a better estimate of $\beta_{j}$, it may actually be a good idea to mis-estimate $W$. This peculiar observation is our first hint that the RUV-4 estimator may be more naturally formulated in the context of a different (or at least more fully specified) model. Indeed, we will see later that the RUV-4 estimator does arise more naturally in the context of a mixed effects model, in which $\alpha$ is explicitly modeled as random.

The differences between RUV-2 and RUV-4 are especially interesting when certain assumptions break down. In particular, we will now provide some intuition to suggest that RUV-4 may outperform RUV-2 when the control genes are not properly specified, or when $k$ is overestimated. We begin with an example in which $k$ is overestimated. The example is essentially the same as those in Figure 3, except that now in truth $k=0$. Nonetheless, we still proceed to estimate $W$ as if we had estimated $\hat{k}=1$. In other words, $\hat{W}=\hat{W}^{(1)}$. Since in truth there is no unwanted variation (W人) term to adjust for, we would ideally like that no adjustment is made; we would like $\hat{b}_{W X}$ to equal 0 and our dotted line to be horizontal. Figure 4 shows three different simulations of this example. As we can see, RUV-4 does a much better job of providing no adjustment when none is needed; the orange dotted lines are relatively horizontal, while the brown dotted lines flap around wildly.

This example is particularly interesting in that it suggests that when performing RUV-4, we may in fact pay only a small price in performance if we overestimate $k$. Indeed, in this particularly simple example it is easy to see that $\mathbb{E}\left[\hat{b}_{W X}^{(\mathrm{RUV}-4)}\right]=0$, and that $\operatorname{Var}\left[\hat{b}_{W X}^{(\mathrm{RUV}-4)}\right]$ approaches 0 as the number of control genes grows large. With a large enough set of control genes, there is effectively no harm at all in overestimating $k$. Figure 5 makes this point using real data. In both the Alzheimer's and Gender datasets, the performance of RUV-2 drops substantially if $K$ is too high. The performance of RUV-4 however remains good even for very high $K$. Indeed RUV-4 performs at least as well as the unadjusted case ( $K=0$ ) for nearly every possible $K$.

Finally, note that although the performance of RUV-4 does decrease somewhat if $K$ is set too large, this is not necessarily an indication that the performance of $\hat{\beta}^{(\mathrm{RUV}-4)}$ is decreasing with large $K$. Estimates of the variances (i.e. the $\hat{\sigma}_{j}^{2}$ ) may instead be to blame. Indeed, if we use standard methods instead of Limma

Figure 4: A comparison of RUV-4 and RUV-2 when $k$ has been overestimated. See main text for commentary. The simulated data were generated as follows: $X=(0,1)^{\prime} ; \epsilon_{i j} \sim \mathrm{~N}\left(0, \frac{1}{4}\right) ; \beta_{j} \sim \mathrm{~N}\left(0, \frac{9}{4}\right)$ for $1 \leq j \leq 50 ; \beta_{j}=0$ for $51 \leq j \leq 1000$.
(Smyth, 2004) to estimate $\hat{\sigma}^{2}$, the performance of RUV-4 is nearly as bad as the performance of RUV-2 for large $K$ (data not shown). The performance of RUV-4 as a whole depends on getting good estimates of both $\beta$ and $\sigma^{2}$. We have demonstrated there is reason to believe that $\hat{\beta}^{(\operatorname{RUV}-4)}$ performs well even for very high $K$. Getting good estimates of $\sigma^{2}$ is a separate challenge. We will return to this point in Section 3.7.

We now consider an example in which the control genes are misspecified. Figure 6A shows an example similar to those in Figure 3. 100 genes are (correctly) designated as control genes, and colored green. Figure 6B shows the same example dataset, but now 110 genes are designated as control genes - the same 100 as in Figure 6A, plus an additional 10 that have been incorrectly designated as control genes. These 10 misspecified control genes are plotted as purple circles filled in with a green dot.

As we can see, the inclusion of these 10 misspecified control genes does not substantially affect the RUV-4 estimate of $\hat{W}$, but does affect the RUV-2 estimate. It is easy to see why the RUV-2 estimate is affected. The additional scatter in the vertical direction introduced by the 10 misspecified control genes "pulls" the principal eigenvector into a more vertical position. Why is the RUV-4 estimate not also affected? The reason is that there is not a strong correlation between $\alpha$ and $\beta$. The misspecified control genes in this example introduce additional vertical scatter, but they are not, for example, systematically too high on the right (where $\alpha$ is positive) and too low on the left (where $\alpha$ is negative). The slope of the regression line is therefore largely unaffected.

We see then that RUV-4 is relatively robust to misspecification of the control genes. As we show in Section 3.5, RUV-4 does not require that $\beta_{c}=0$ but only that $\beta_{c} \alpha_{c}^{\prime}=0$. This is clearly a much weaker requirement of the control genes. It is also a fairly mysterious requirement that is hard to interpret and nearly impossible to verify. Thus, the extent to which we can exploit this weaker requirement is limited. For example, we may be tempted to reason loosely that $W$ contains mainly technical factors (e.g. temperature of the scanner, etc.), and that the effects of the technical factors (i.e. $\alpha$ ) should not relate in any systematic way to the effects of biological factors (i.e. $\beta$ ), and thus that $\beta_{c} \alpha_{c}^{\prime} \approx 0$. Why, we might reason, should the genes that are up-regulated by cancer also be the genes whose observations are biased upwards by an overly warm scanner? And yet, this could very well be. For example, if the genes that are up-regulated by cancer tend to be genes that are highly expressed, and genes whose observations are biased upwards by an overly warm scanner also tend to be genes that are highly expressed, we would get just that scenario. Instead, we view the relatively weak requirements placed on the control genes by RUV-4 not as something to exploit per se, but rather as a comforting reassurance that even if we accidentally misspecify some control genes, we may still get lucky and end up OK - or at least not as badly off as if we had used RUV-2.

Figures 6C and 6D provide an even starker example of the difference between RUV-2 and RUV-4 when

Figure 5: Comparison of the performance of RUV-2 (brown cross) and RUV-4 (orange circle) as a function of $K$ in the Alzheimer's and Gender studies. The horizontal axis is $K . K=0$ corresponds to no adjustment. For each $K$, genes were ranked by $p$-value; the vertical axis is the number of $\mathrm{X} / \mathrm{Y}$ genes ranked in the top 60. Data were preprocessed. Housekeeping genes were used as control genes. $p$-values were computed using Limma.
control genes are misspecified. As in Figure 6A, in Figure 6C there are 100 genes correctly designated as control genes. Figure 6D shows the same example dataset as Figure 6C, but with an additional 10 misspecified control genes. The difference between Figures 6C and 6D and Figures 6A and 6B is that in Figures 6C and $6 \mathrm{D}, k$ has been overestimated. As in Figure 5, $k=0$ but $K=1$. The combination of misspecified control genes and an overestimated $k$ is particularly damaging to RUV-2. Since there is no more unwanted variation, the only remaining systematic variation in the control genes comes from the misspecified control genes and is in the $X$ direction. As we can see, the slope of the brown dotted line in Figure 6D is much steeper than in Figure 6C. In this example, RUV-2 clearly detects - and adjusts away - the biological factor of interest. On the other hand, the slope of the orange dotted line is largely unaffected. RUV-4 is relatively robust to misspecification of control genes and overestimation of $k$, even in combination.

Figure 6: A comparison of RUV-4 and RUV-2 when control genes have been misspecified. See main text for commentary. The simulated data in A and B were generated as follows: $X=(0,1)^{\prime} ; W=(1,0.5)^{\prime}$; $\alpha_{j} \sim \mathrm{~N}\left(0, \frac{1}{4}\right) ; \epsilon_{i j} \sim \mathrm{~N}\left(0, \frac{1}{4}\right) ; \beta_{j} \sim \mathrm{~N}\left(0, \frac{9}{4}\right)$ for $1 \leq j \leq 50 ; \beta_{j}=0$ for $51 \leq j \leq 1000$. The simulated data in C and D were generated as follows: $X=(0,1)^{\prime} ; \epsilon_{i j} \sim \mathrm{~N}\left(0, \frac{1}{4}\right) ; \beta_{j} \sim \mathrm{~N}\left(0, \frac{9}{4}\right)$ for $1 \leq j \leq 50 ; \beta_{j}=0$ for $51 \leq j \leq 1000$.

### 3.5 Statistical Properties of RUV-4

We now explore the bias and variance of $\hat{\beta}$. Calculating the bias and variance requires that we specify whether $\alpha$ is to be regarded as fixed or random. Ideally we would like to analyze the bias and variance of $\hat{\beta}$ under the assumption that $\alpha$ is fixed. However, this is difficult. Therefore we will occasionally regard $\alpha$ as random. To make the discussion consistent, we will always formally treat $\alpha$ as if it is random, but condition on $\alpha$ when appropriate.

Unfortunately, exact calculations of the bias and variance are difficult if not impossible for a variety of reasons, so instead we focus on simplifications and approximations that are both illuminating and reasonably accurate. One complication is that the statistical properties of $\hat{\beta}_{j}$ depend on whether the $j^{\text {th }}$ gene is a control gene or not. In what follows we limit our discussion to a gene $j_{\bar{c}}$ that is not a control gene.

Another complication when calculating the bias and variance of $\hat{\beta}$ is that we must know the statistical properties of $\hat{W}_{0}$ and $\hat{\alpha}$. These properties depend on the choice of factor analysis method - and are difficult to calculate in any case. We therefore simplify the situation by making use of a hypothetical idealized factor analysis method. Specifically, we suppose that $\hat{W}_{0}=W_{0}$ and thus that $\hat{\alpha}=\left(W_{0}^{\prime} W_{0}\right)^{-1} W_{0}^{\prime} Y$. In other words, we imagine we have access to an idealized factor analysis method that perfectly estimates $W_{0}$; with this we then additionally estimate $\alpha$ by OLS as specified in (23). This simplification is not entirely unrealistic; with tens of thousands of genes, estimates of $W_{0}$ can be quite good.

### 3.5.1 Results for fixed $\alpha$

We begin by defining

$$
\begin{aligned}
& \zeta \equiv\left(X^{\prime} X\right)^{-1} X^{\prime} \epsilon \\
& \xi \equiv\left(W_{0}^{\prime} W_{0}\right)^{-1} W_{0}^{\prime} \epsilon
\end{aligned}
$$

and noting that

$$
\begin{aligned}
\zeta_{j_{\bar{c}}} & \sim \mathrm{~N}\left(0, \sigma_{j_{\bar{c}}}^{2}\right) \\
\xi_{\star j_{\bar{c}}} & \sim \mathrm{~N}\left(0, \sigma_{j_{\bar{c}}}^{2} I\right) \\
\hat{b}_{W X} & \Perp \zeta_{j_{\bar{c}}} \\
\hat{b}_{W X} & \Perp \xi_{\star j_{\bar{c}}} \\
\zeta_{j_{\bar{c}}} & \Perp \xi_{\star j_{\bar{c}}} .
\end{aligned}
$$

It follows that

$$
\begin{aligned}
\hat{\beta} & =\left(X^{\prime} X\right)^{-1} X^{\prime}(Y-\hat{W} \hat{\alpha}) \\
& =\left(X^{\prime} X\right)^{-1} X^{\prime}\left[X \beta+\left(W_{0}+X b_{W X}\right) \alpha+\epsilon-\left(W_{0}+X \hat{b}_{W X}\right) \hat{\alpha}\right] \\
& =\beta+b_{W X} \alpha-\hat{b}_{W X} \hat{\alpha}+\zeta \\
& =\beta+b_{W X} \alpha-\hat{b}_{W X}\left[\alpha+\left(W_{0}^{\prime} W_{0}\right)^{-1} W_{0}^{\prime} \epsilon\right]+\zeta \\
& =\beta+\left(b_{W X}-\hat{b}_{W X}\right) \alpha+\zeta-\hat{b}_{W X} \xi
\end{aligned}
$$

and that

$$
\begin{aligned}
\mathbb{E}\left[\hat{\beta}_{j_{\bar{c}}}\right]= & \beta_{j_{\bar{c}}}+\mathbb{E}\left[b_{W X}-\hat{b}_{W X}\right] \mathbb{E}\left[\alpha_{\star j_{\bar{c}}}\right] \\
\operatorname{Var}\left[\hat{\beta}_{j_{\bar{c}}}\right]= & \operatorname{Var}\left[\zeta_{j_{\bar{c}}}\right]+\operatorname{Var}\left[\hat{b}_{W X}\left(\alpha_{\star j_{\bar{c}}}+\xi_{\star j_{\bar{c}}}\right)\right] \\
= & \sigma_{j_{\bar{c}}}^{2}+\mathbb{E}\left[\alpha_{\star j_{\bar{c}}}^{\prime}\right] \operatorname{Var}\left[\hat{b}_{W X}\right] \mathbb{E}\left[\alpha_{\star j_{\bar{c}}}\right]+\mathbb{E}\left[\hat{b}_{W X}\right] \operatorname{Var}\left[\alpha_{\star j_{\bar{c}}}+\xi_{\star j_{\bar{c}}}\right] \mathbb{E}\left[\hat{b}_{W X}^{\prime}\right]+ \\
& \operatorname{tr}\left(\operatorname{Var}\left[\hat{b}_{W X}\right]^{\frac{1}{2}} \operatorname{Var}\left[\alpha_{\star j_{\bar{c}}}+\xi_{\star j_{\bar{c}}}\right] \operatorname{Var}\left[\hat{b}_{W X}\right]^{\frac{1}{2}}\right) .
\end{aligned}
$$

If we now condition on $\alpha_{j_{\bar{c}}}$ we find that

$$
\begin{aligned}
\mathbb{E}\left[\hat{\beta}_{j_{\bar{c}}} \mid \alpha_{\star j_{\bar{c}}}\right] & =\beta_{j_{\bar{c}}}+\mathbb{E}\left[b_{W X}-\hat{b}_{W X}\right] \alpha_{\star j_{\bar{c}}} \\
\operatorname{Var}\left[\hat{\beta}_{j_{\bar{c}}} \mid \alpha_{\star j_{\bar{c}}}\right] & =\sigma_{j_{\bar{c}}}^{2}+\alpha_{\star j_{\bar{c}}}^{\prime} \operatorname{Var}\left[\hat{b}_{W X}\right] \alpha_{\star j_{\bar{c}}}+\sigma_{j_{\bar{c}}}^{2} \mathbb{E}\left[\hat{b}_{W X}\right] \mathbb{E}\left[\hat{b}_{W X}^{\prime}\right]+\sigma_{j_{\bar{c}}}^{2} \operatorname{tr}\left(\operatorname{Var}\left[\hat{b}_{W X}\right]\right)
\end{aligned}
$$

and conclude

$$
\begin{align*}
\operatorname{Bias}\left[\hat{\beta}_{j_{\bar{c}}} \mid \alpha_{\star j_{\bar{c}}}\right] & =\mathbb{E}\left[b_{W X}-\hat{b}_{W X}\right] \alpha_{\star j_{\bar{c}}}  \tag{38}\\
\operatorname{Var}\left[\hat{\beta}_{j_{\bar{c}}} \mid \alpha_{\star j_{\bar{c}}}\right] & =\sigma_{j_{\bar{c}}}^{2}\left\{1+\mathbb{E}\left[\hat{b}_{W X}\right] \mathbb{E}\left[\hat{b}_{W X}^{\prime}\right]\right\}+\sigma_{j_{\bar{c}}}^{2} \operatorname{tr}\left(\operatorname{Var}\left[\hat{b}_{W X}\right]\right)+\alpha_{\star j_{\bar{c}}}^{\prime} \operatorname{Var}\left[\hat{b}_{W X}\right] \alpha_{\star j_{\bar{c}}} \tag{39}
\end{align*}
$$

Recall that these expressions do not take into account any bias or variance introduced by the estimation of $W_{0}$, but are otherwise exact.

### 3.5.2 Discussion: $\mathbb{E}\left[\hat{b}_{W X}\right]$

We now consider $\mathbb{E}\left[\hat{b}_{W X}\right]$. As we will soon see, this leads us to an error-in-variables regression problem. Begin by noting

$$
\begin{align*}
\hat{b}_{W X}= & b_{Y_{c} X} \hat{\alpha}_{c}^{\prime}\left(\hat{\alpha}_{c} \hat{\alpha}_{c}^{\prime}\right)^{-1}  \tag{40}\\
= & \left(X^{\prime} X\right)^{-1} X^{\prime} Y_{c}\left(\alpha_{c}+\xi_{c}\right)^{\prime}\left[\left(\alpha_{c}+\xi_{c}\right)\left(\alpha_{c}+\xi_{c}\right)^{\prime}\right]^{-1}  \tag{41}\\
= & \left(\beta_{c}+b_{W X} \alpha_{c}+\zeta_{c}\right)\left(\alpha_{c}+\xi_{c}\right)^{\prime}\left[\left(\alpha_{c}+\xi_{c}\right)\left(\alpha_{c}+\xi_{c}\right)^{\prime}\right]^{-1}  \tag{42}\\
= & \left(b_{W X} \alpha_{c}+\zeta_{c}\right)\left(\alpha_{c}+\xi_{c}\right)^{\prime}\left[\left(\alpha_{c}+\xi_{c}\right)\left(\alpha_{c}+\xi_{c}\right)^{\prime}\right]^{-1} \\
& +\beta_{c}\left(\alpha_{c}+\xi_{c}\right)^{\prime}\left[\left(\alpha_{c}+\xi_{c}\right)\left(\alpha_{c}+\xi_{c}\right)^{\prime}\right]^{-1} . \tag{43}
\end{align*}
$$

If the control gene assumption $\beta_{c}=0$ holds, the second term vanishes, and we are left with

$$
\hat{b}_{W X}=\left(b_{W X} \alpha_{c}+\zeta_{c}\right)\left(\alpha_{c}+\xi_{c}\right)^{\prime}\left[\left(\alpha_{c}+\xi_{c}\right)\left(\alpha_{c}+\xi_{c}\right)^{\prime}\right]^{-1}
$$

This would be the OLS estimator for the parameter $b_{W X}$ in a regression of the "response variable" $b_{W X} \alpha_{c}+\zeta_{c}$ on the "explanatory variable" $\alpha_{c}$, were it not for the fact that the "explanatory variable" $\alpha_{c}$ has been corrupted by the error term $\xi_{c}$.

### 3.5.3 Results for random $\alpha$

Error-in-variables regression problems are difficult to analyze, and general expressions for the bias and variance are not known. We are therefore unable to analyze $\mathbb{E}\left[\hat{b}_{W X}\right]$ in general. Instead, we attempt to gain some insight into $\mathbb{E}\left[\hat{b}_{W X}\right]$ by considering a simple, specific example. Assume that for all control genes

$$
\begin{align*}
\alpha_{\star j_{c}} & \sim \mathrm{~N}\left(0, \Psi^{2}\right)  \tag{44}\\
\sigma_{j_{c}}^{2} & =\sigma_{0}^{2} \tag{45}
\end{align*}
$$

where $\sigma_{0}^{2}$ is some fixed constant. Assume without a loss in generality that $\Psi^{2}$ is diagonal. Assume also that $n_{c}$ is large. Then

$$
\begin{aligned}
\hat{b}_{W X} & =\left(b_{W X} \alpha_{c}+\zeta_{c}\right)\left(\alpha_{c}+\xi_{c}\right)^{\prime}\left[\left(\alpha_{c}+\xi_{c}\right)\left(\alpha_{c}+\xi_{c}\right)^{\prime}\right]^{-1} \\
& =\left(\frac{b_{W X} \alpha_{c} \alpha_{c}^{\prime}}{n_{c}}+\frac{\zeta_{c} \alpha_{c}^{\prime}}{n_{c}}+\frac{b_{W X} \alpha_{c} \xi_{c}^{\prime}}{n_{c}}+\frac{\zeta_{c} \xi_{c}^{\prime}}{n_{c}}\right)\left(\frac{\alpha_{c} \alpha_{c}^{\prime}}{n_{c}}+\frac{\xi_{c} \alpha_{c}^{\prime}}{n_{c}}+\frac{\alpha_{c} \xi_{c}^{\prime}}{n_{c}}+\frac{\xi_{c} \xi_{c}^{\prime}}{n_{c}}\right)^{-1} \\
& \approx b_{W X} \Psi^{2}\left(\Psi^{2}+\sigma_{0}^{2} I\right)^{-1} .
\end{aligned}
$$

We therefore see that the entries of $\hat{b}_{W X}$ are asymptotically biased towards 0 . In particular, the $(1, l)^{\text {th }}$ entry of $\hat{b}_{W X}$ (which we denote $\left.\left(\hat{b}_{W X}\right)_{l}\right)$ is asymptotically biased by a factor of $\frac{\psi_{l}^{2}}{\psi_{l}^{2}+\sigma_{0}^{2}}$, where $\psi_{l}^{2}$ is the $l^{\text {th }}$ diagonal entry of $\Psi^{2}$. This observation agrees with the intuition we developed in Section (3.4) - $\hat{b}_{W X}$ is biased towards 0 , and the bias grows stronger as the unwanted variation becomes weaker.

Under assumptions (44) and (45) and the assumption that $n_{c}$ is large, we may simplify (38) as

$$
\begin{equation*}
\operatorname{Bias}\left[\hat{\beta}_{j_{\bar{c}}} \mid \alpha_{\star j_{\bar{c}}}\right] \approx b_{W X}\left(\Psi^{2} / \sigma_{0}^{2}+I\right)^{-1} \alpha_{\star j_{\bar{c}}} \tag{46}
\end{equation*}
$$

Moreover, under the same assumptions $\operatorname{Var}\left[\hat{b}_{W X}\right] \approx 0$, so we may we may simplify (39) as

$$
\begin{align*}
\operatorname{Var}\left[\hat{\beta}_{j_{\bar{c}}} \mid \alpha_{\star j_{\bar{c}}}\right] & \approx \sigma_{j_{\bar{c}}}^{2}\left\{1+\mathbb{E}\left[\hat{b}_{W X}\right] \mathbb{E}\left[\hat{b}_{W X}^{\prime}\right]\right\}  \tag{47}\\
& \approx \sigma_{j_{\bar{c}}}^{2}\left(1+b_{W X} \Psi^{4}\left(\Psi^{2}+\sigma_{0}^{2} I\right)^{-2} b_{W X}^{\prime}\right) \tag{48}
\end{align*}
$$

From this we conclude

$$
\operatorname{MSE}\left[\hat{\beta}_{j_{\bar{c}}} \mid \alpha_{\star j_{\bar{c}}}\right] \approx \sigma_{j_{\bar{c}}}^{2}+b_{W X}\left[\left(\Psi^{2} / \sigma_{0}^{2}+I\right)^{-1} \alpha_{\star j_{\bar{c}}} \alpha_{\star j_{\bar{c}}}^{\prime}\left(\Psi^{2} / \sigma_{0}^{2}+I\right)^{-1}+\sigma_{j_{\bar{c}}}^{2} \Psi^{4}\left(\Psi^{2}+\sigma_{0}^{2} I\right)^{-2}\right] b_{W X}^{\prime}(49)
$$

This is a complicated expression and somewhat difficult to interpret. It is clear that, unless $b_{W X}=0$, the MSE can be arbitrarily large depending on the value of $\alpha_{\star j_{\bar{c}}}$. However, it is not clear how large the MSE might be in a "typical" case. To investigate this question, we will now assume

$$
\begin{align*}
\alpha_{\star j_{\bar{c}}} & \sim \mathrm{~N}\left(0, \Psi^{2}\right)  \tag{50}\\
\sigma_{j_{\bar{c}}}^{2} & =\sigma_{0}^{2} \tag{51}
\end{align*}
$$

just as we did for the control genes. Under these assumptions

$$
\begin{align*}
\operatorname{MSE}\left[\hat{\beta}_{j}\right] & \approx \sigma_{0}^{2}+b_{W X}\left[\left(\Psi^{2} / \sigma_{0}^{2}+I\right)^{-1} \Psi^{2}\left(\Psi^{2} / \sigma_{0}^{2}+I\right)^{-1}+\sigma_{0}^{2} \Psi^{4}\left(\Psi^{2}+\sigma_{0}^{2} I\right)^{-2}\right] b_{W X}^{\prime}  \tag{52}\\
& =\sigma_{0}^{2}+b_{W X}\left(\Psi^{2} / \sigma_{0}^{2}+I\right)^{-2}\left(\Psi^{2}+\Psi^{4} / \sigma_{0}^{2}\right) b_{W X}^{\prime}  \tag{53}\\
& =\sigma_{0}^{2}+b_{W X} \Psi^{2}\left(\Psi^{2} / \sigma_{0}^{2}+I\right)^{-1} b_{W X}^{\prime}  \tag{54}\\
& =\sigma_{0}^{2}\left[1+b_{W X} \Psi^{2}\left(\Psi^{2}+\sigma_{0}^{2} I\right)^{-1} b_{W X}^{\prime}\right] . \tag{55}
\end{align*}
$$

It may not be immediately obvious whether (55) is "good" or "bad." For sake of comparison, suppose we knew $W$, and could simply estimate $\beta$ by OLS. Designate this hypothetical estimator by $\hat{\beta}^{(\mathrm{OLS})}$. Now, $\hat{\beta}^{(\mathrm{OLS})}$ is unbiased, so the MSE is simply the variance:

$$
\begin{equation*}
\operatorname{MSE}\left[\hat{\beta}_{j}^{(\mathrm{OLS})}\right]=\sigma_{0}^{2}\left(1+b_{W X} b_{W X}^{\prime}\right) \tag{56}
\end{equation*}
$$

(See Section A. 2 for a proof.) Thus, under assumptions (44), (45), (50), (51) and the assumption that $n_{c}$ is large, we see that $\operatorname{MSE}\left[\hat{\beta}_{j}^{(\mathrm{RUV}-4)}\right]<\operatorname{MSE}\left[\hat{\beta}_{j}^{(\mathrm{OLS})}\right]$, at least up to approximation:

$$
\begin{align*}
\operatorname{MSE}\left[\hat{\beta}_{j}^{(\mathrm{OLS})}\right]-\operatorname{MSE}\left[\hat{\beta}_{j}^{(\mathrm{RUV}-4)}\right] & \approx \sigma_{0}^{2} b_{W X}\left[I-\Psi^{2}\left(\Psi^{2}+\sigma_{0}^{2} I\right)^{-1}\right] b_{W X}^{\prime}  \tag{57}\\
& =\sigma_{0}^{2} \sum_{l=1}^{k} \frac{\sigma_{0}^{2}}{\psi_{l}^{2}+\sigma_{0}^{2}}\left(b_{W X}\right)_{1 l}^{2} \tag{58}
\end{align*}
$$

### 3.5.4 Discussion: Random or Fixed?

In the previous section we analyzed the RUV-4 estimator under the assumption that $\alpha$ is random. This was motivated by the fact that it is very difficult to analyze the RUV-4 estimator under the assumption that $\alpha$ is fixed. Regarding $\alpha$ as random allowed us to develop some intuition about the behavior of the RUV-4 estimator that we might not have been able to develop otherwise. We found that under our assumptions the RUV-4 estimator actually has a smaller MSE than the (hypothetical) OLS estimator. This result may be surprising at first, but can be easily understood as RUV-4 exploiting the assumption that the $\alpha_{\star j_{\bar{c}}}$ and the $\alpha_{\star j_{c}}$ are drawn from the same normal distribution. The conclusion is that RUV-4 has the potential to outperform OLS. For it to do so, however, the control genes must satisfy an additional criterion. The control genes must not only be uninfluenced by $X$ yet influenced by $W$, but they must also be influenced by $W$ in much the same way as all of the other genes are. The $\alpha_{\star j_{c}}$ must be "representative" of the $\alpha_{\star j_{\bar{c}}}$.

In Section 3.7 we will reformulate the RUV-4 estimator. Under this reformulation, we will see that the RUV-4 estimator arises very naturally from a model in which $\alpha$ is random. In Section 5 we will observe that RUV-4 works very well when applied to real datasets.

A natural question to ask, then, is whether we should regard $\alpha$ as random. This question does not have an easy answer. The RUV model is highly artificial. We regard the model primarily as a source of inspiration for new methods; the value of these methods must then be established independently, by testing how well they perform on real data. In this context, it may be wise to regard $\alpha$ as random. RUV-4 is an effective method that arises naturally from a model in which $\alpha$ is random. Regarding $\alpha$ as random may ultimately inspire ideas for even more effective methods.

On the other hand, neither the effectiveness nor the "naturalness" of an estimator can ultimately justify the model from which the estimator arose. Moreover, despite the fact the RUV model is artificial, there is an obvious interest in keeping the model as realistic as feasible. In this context, it seems wise to regard $\alpha$ as fixed. Random effects seem implausible; we are unaware of any physical argument that would justify regarding $\alpha$ as random, let alone the distributional assumptions we have imposed on $\alpha$. For example, if $\alpha_{4,25}$ is the effect of temperature on the observed expression level of the $25^{\text {th }}$ probe, should we not expect $\alpha_{4,25}$ to be dictated by the physical and chemical properties of the $25^{\text {th }}$ probe, and thus to be constant from one experiment to the next?

Instead of regarding $\alpha$ as random, it may be better to regard $\alpha$ as fixed with some (non-random) distribution that can often be reasonably approximated in practice by a normal distribution. The distinction may seem pedantic, but we believe regarding $\alpha$ in this manner is useful. For example, it serves as a reminder that some $\alpha_{i j}$ may be serious outliers, and that these outliers may reveal interesting information upon further investigation. It also serves as a reminder that different genes may have different biases. It may be that $\hat{\beta}$ is consistently biased one way or another for genes with high GC content, or for genes that are highly expressed. If these biases are consistent from one experiment to the next, they may lead to inaccurate conclusions, despite the replication. We believe it is helpful to keep such considerations in mind.

To summarize, there is no clear answer as to whether $\alpha$ should be regarded as fixed or random. Both points of view are useful in their own way. Moreover, a decisive answer may not be necessary. In Section 3.8 we will provide still another framework for understanding RUV-4 that partly sidesteps the issue. Finally, and most importantly, we reiterate that we have seen that the superior performance of RUV-4 relies on the $\alpha_{\star j_{c}}$ being "representative" of the $\alpha_{\star j_{\bar{c}}}$. This clearly has important practical implications for choosing a set of control genes.

### 3.6 Practical considerations for RUV-4

We now consider several topics including the estimation of $\sigma^{2}$, $\operatorname{Var}\left[\hat{\beta}_{j_{\bar{c}}} \mid \alpha_{\star j_{\bar{c}}}\right]$ and $k$; the handling of covariates; the consequences of misspecified control genes; and the consequences of under- or over-estimating $k$. We continue to formally treat $\alpha$ as if it is random, conditioning when appropriate.

### 3.6.1 Estimating $\sigma^{2}$ and $\operatorname{Var}\left[\hat{\beta}_{j_{\bar{c}}} \mid \alpha_{\star j_{\bar{c}}}\right]$

Suppose we want to estimate $\sigma_{j}^{2}$. If we disregard the fact that $\hat{W}$ is an estimate and simply treat it as $W$, the "standard" estimate for $\sigma_{j}^{2}$ is:

$$
\begin{align*}
\hat{\sigma}_{j}^{2} & \equiv \frac{1}{m-\hat{k}-1} \sum_{i=1}^{m}\left(Y_{i j}-X \hat{\beta}_{j}-\hat{W} \hat{\alpha}_{\star j}\right)^{2}  \tag{59}\\
& =\frac{1}{m-\hat{k}-1}\left(R_{(X \mid \hat{W})} Y_{\star j}\right)^{\prime}\left(R_{(X \mid \hat{W})} Y_{\star j}\right) . \tag{60}
\end{align*}
$$

$R_{(X \mid \hat{W})}$ depends only on the column space of $(X \mid \hat{W})$, and the columns of $X$ and $\hat{W}_{0}$ together form a basis of $\Re[(X \mid \hat{W})]$, so $R_{(X \mid \hat{W})}=R_{\left(X \mid \hat{W}_{0}\right)}$. Thus $\hat{\sigma}_{j}^{2}$ is independent of our estimate of $b_{W X}$. Indeed, if $\hat{W}_{0}=W_{0}$ then $R_{(X \mid \hat{W})}=R_{(X \mid W)}$ and $\hat{\sigma}_{j}^{2}$ is identical to the "standard" estimate of $\sigma_{j}^{2}$ that we would get if $W$ were known.

Now suppose we want to estimate $\operatorname{Var}\left[\hat{\beta}_{j_{\bar{c}}} \mid \alpha_{\star j_{\bar{c}}}\right]$. Recall that when $n_{c}$ is large,

$$
\begin{align*}
\operatorname{Var}\left[\hat{\beta}_{j_{\bar{c}}} \mid \alpha_{\star j_{\bar{c}}}\right] & \approx \sigma_{j_{\bar{c}}}^{2}\left\{1+\mathbb{E}\left[\hat{b}_{W X}\right] \mathbb{E}\left[\hat{b}_{W X}^{\prime}\right]\right\}  \tag{61}\\
& \approx \sigma_{j_{\bar{c}}}^{2}\left(1+\hat{b}_{W X} \hat{b}_{W X}^{\prime}\right) \tag{62}
\end{align*}
$$

Given our estimate $\hat{\sigma}_{j_{\bar{c}}}^{2}$ of $\sigma_{j_{\bar{c}}}^{2}$, we may therefore estimate $\operatorname{Var}\left[\hat{\beta}_{j_{\bar{c}}} \mid \alpha_{\star j_{\bar{c}}}\right]$ as

$$
\begin{equation*}
\widehat{\operatorname{Var}}\left[\hat{\beta}_{j_{\bar{c}}} \mid \alpha_{\star j_{\bar{c}}}\right] \equiv \hat{\sigma}_{j_{\bar{c}}}^{2}\left(1+\hat{b}_{W X} \hat{b}_{W X}^{\prime}\right) \tag{63}
\end{equation*}
$$

This is a particularly appealing result since (63) is equivalent to the standard estimate of Var $\left[\hat{\beta}_{j_{\bar{c}}} \mid \alpha_{\star j_{\bar{c}}}\right]$ that we would calculate if we simply treated $\hat{W}$ as $W$ and ran a standard regression (see Section A. 2 of the SM for proof).

To summarize, if $n_{c}$ is large and $\hat{W}_{0} \approx W_{0}$ then plugging in $\hat{W}$ for $W$ and and estimating $\sigma^{2}$ and $\operatorname{Var}\left[\hat{\beta}_{j_{\bar{c}}} \mid \alpha_{\star j_{\bar{c}}}\right]$ in the standard way will provide satisfactory results. Thus, once we have computed $\hat{W}$ using RUV-4, standard methods and software can be used to estimate variances, calculate $t$ statistics and $p$-values, etc. However, we should note that even under these "ideal" conditions, $p$-values computed in the standard way are not necessarily reliable, since $\hat{\beta}_{j_{\bar{c}}}$ is biased (conditional on $\alpha_{\star j_{\bar{c}}}$ ). Even more importantly, we note that a major implicit assumption in our analysis is that we have properly estimated $k$. Serious problems may occur if we mis-estimate $k$. See Section 3.6.5. Finally, note that strictly speaking (63) is only appropriate for non-control genes. In practice however, we apply it to the control genes as well.

### 3.6.2 Handling Covariates, and the Case $p>1$

In (7) we made the simplifying assumptions that there is no $Z$ term and that $p=1$. We now consider what to do when this is not true. We will first consider the case that $p=1$ but that observed covariates $Z$ are available. We will then consider the case that $p>1$. We find that both cases can be reduced to the case that there is no $Z$ term and $p=1$. However, there is more than one way to reduce to the case that there is no $Z$ term and $p=1$, and it is not always clear which way is best.

Suppose observed covariates $Z$ are available. There are two options. The first is to simply ignore them. RUV-4 can then estimate these unwanted factors and incorporate them into $\hat{W}$ just as it would any other unwanted factors. This is often the best option. Gagnon-Bartsch and Speed (2012) argue that the observed covariates that one has available are often only proxies for the "true" unwanted factors. For example, "batch" itself does not cause "batch effects." Batch effects are the result of other factors (e.g. temperature) that are
correlated with batch. Compared to the proxy variables in $Z$, factor analysis may provide a better estimate of the "true" unwanted factors.

The second option is to explicitly adjust for $Z$. Multiplying both sides of (1) by $Z_{\perp}^{\prime}$ yields

$$
\begin{equation*}
Z_{\perp}^{\prime} Y=\left(Z_{\perp}^{\prime} X\right) \beta+\left(Z_{\perp}^{\prime} W\right) \alpha+Z_{\perp}^{\prime} \epsilon \tag{64}
\end{equation*}
$$

Note that

$$
Z_{\perp}^{\prime} \epsilon_{\star j} \sim N\left(0, \sigma_{j}^{2} I_{(m-q) \times(m-q)}\right)
$$

We may therefore simply use $Z_{\perp}^{\prime} Y$ and $Z_{\perp}^{\prime} X$ instead of $Y$ and $X$, and proceed as we would in the case that there is no $Z$ term. Note that we have effectively "projected" $Z$ away. However, strictly speaking this is not a "projection" in the technical sense, since we premultiply by $Z_{\perp}$ instead of by $R_{Z}$; instead of mapping the data from $\mathbb{R}^{m}$ to a $m-q$ dimensional subspace of $\mathbb{R}^{m}$, we map the data from $\mathbb{R}^{m}$ to $\mathbb{R}^{m-q}$.

When should we explicitly adjust for $Z$ and when should we just ignore it? A few observations are relevant. One such observation is that a poor proxy variable can create more problems than it solves. Assume that in truth

$$
\begin{equation*}
Y=X \beta+Z \gamma+\epsilon \tag{65}
\end{equation*}
$$

but that we regress $Y$ on $X$ and $\tilde{Z}$, where $\tilde{Z}$ is correlated with but not equal to $Z$. It is possible that the bias of $\hat{\beta}$ in this case is even larger than if we had simply regressed $Y$ on $X$ and ignored $\tilde{Z}$. This is of particular concern if $\tilde{Z}$ is highly correlated with $X$. Another observation is that by explicitly including a $Z$ term, we are effectively treating $\gamma$ as fixed. By letting RUV-4 incorporate $Z$ into $W$ and $\gamma$ into $\alpha$, we are effectively treating $\gamma$ as random. By explicitly including a $Z$ term, we may therefore lose some of the performance advantage offered by RUV-4. A final observation is that explicitly adjusting for $Z$ may hinder our ability to estimate $W$ and $\alpha$. If $W$ and $Z$ are correlated, projecting away $Z$ will also project away some of $W$. This will make the estimation of $W$ and $\alpha$ more difficult. If the factors contained in $Z$ are less important than those contained in $W$ (i.e $Z \gamma$ is "smaller" than $W \alpha$ ), it may be better to ignore $Z$ for sake of a better estimate of $W \alpha$. A rather extreme example may help make this point more clear. Suppose there are $m-1$ known covariates. Suppose that none of these covariates has a strong influence on $Y$, i.e. $\gamma$ is "small." Adjusting for these $m-1$ covariates may remove the relatively minor bias of the $Z \gamma$ term, but it will also leave us with only one dimension for $\hat{W}$ ! Taken together, these observations tend to suggest that $Z$ should generally be ignored.

However, there is an important exception. Consider the case that $\gamma$ is sparse. Suppose that we leave $Z$ out of the model. Since only a few genes exhibit the effects of $Z$, the factor analysis routine may not properly estimate $Z$ and incorporate it into $W$. This may cause problems. The problems are somewhat different depending on whether or not $X$ is correlated with $Z$. We discuss both cases in turn.

Suppose first that $Z$ is strongly correlated with $X$. Suppose that gene $j$ is one of the few genes such that $\gamma_{j} \neq 0$. If we do not explicitly adjust for $Z, \hat{\beta}_{j}$ may be strongly biased. If in truth $\beta_{j}=0$, we may falsely conclude that $\beta_{j} \neq 0$. In other words, we may be led to false discoveries. On the other hand, suppose that in truth $\beta_{j} \neq 0$. We would likely correctly conclude that $\beta_{j} \neq 0$ (barring a very unfortunate cancellation of the $X \beta_{j}$ and $Z \gamma_{j}$ terms). However, $\hat{\beta}_{j}$ would still be biased, and perhaps even the sign would be wrong. This would be quite unfortunate. Since gene $j$ is in fact differentially expressed with respect to $X$, gene $j$ - and the actual value of $\beta_{j}$ - is presumably of substantial scientific interest.

Suppose now that $Z$ is not strongly correlated with $X$. We do not need to worry that omitting $Z$ from the model will seriously bias $\beta_{j}$. However, the estimate $\hat{\sigma}_{j}^{2}$ of $\sigma_{j}^{2}$ may be inflated, as the $Z \gamma$ will still be present in the residuals. If in truth $\beta_{j}=0$, an inflated $\hat{\sigma}_{j}^{2}$ is not of much concern. However, if in truth $\beta_{j} \neq 0$, an inflated $\hat{\sigma}_{j}^{2}$ will lead to a drop in power. We might fail to discover that gene $j$ is differentially expressed with respect to $X$.

Nonetheless, our conclusion is not simply "if $\gamma$ is sparse, include $Z$." A better motto might be "if $\gamma$ is sparse, proceed with caution." If $Z$ suffers from measurement error, or is simply a proxy for some other variable, it may still be best to leave $Z$ out. Moreover, our discussion so far has been far from complete. Additional complications arise, for example, if $Z$ is correlated with $W$. A complete discussion is beyond the scope of this paper. On balance, if $Z$ is important, if $Z$ is well-measured, if $q$ (the number of columns of $Z$ )
is small, and if $\gamma$ is sparse, it is probably best to include $Z$. This is especially true if we believe that both $\beta$ and $\gamma$ are sparse, and that the few genes for which $\beta$ is non-zero are also the few genes for which $\gamma$ is non-zero. Still, this is only a rule of thumb. Repeating the analysis both with and without $Z$ and inspecting the results seems reasonable.

We now consider the case that $p>1$. There are three ways to handle this case. However, two of the three ways turn out to be equivalent, so effectively there are only two ways to handle the case $p>1$. We now describe the three possibilities. The first strategy to handle the case $p>1$ is to proceed with the RUV-4 algorithm exactly as described in Section 3.3.1; nothing in the procedure requires that $p=1$. Of course, we do require that $p<m$. The second strategy to handle the case $p>1$ is to run RUV-4 $p$ times. Each time we redefine $X$ to be just a single column of the original $X$, and ignore the other columns. The third strategy to handle the case $p>1$ is to run RUV-4 $p$ times. Each time we redefine $X$ to be just a single column of the original $X$, and move the remaining columns of $X$ to $Z$; we then explicitly adjust for this " $Z$."

It turns out that the first and the third strategies are equivalent; $\hat{\beta}, \hat{\sigma}^{2}, p$-values, etc. all are identical. We may therefore limit our attention to the second and third strategies. In both strategies, we run RUV-4 $p$ times. Each time, we select a single column of $X$ to be the factor of interest. Denote this column of $X$ by $\tilde{X}$. The remaining columns of $X$ play the role of observed covariates. Denote these columns by $\tilde{Z}$ (no relation to the $\tilde{Z}$ mentioned above). The difference between strategies two and three is whether or not we explicitly adjust for $\tilde{Z}$.

Which strategy is better? Once again, there is no clear answer. All of the considerations regarding whether or not to include $Z$ continue to apply. However, there are additional complications as well. For example, we have assumed that $\beta_{c}=0$. It follows that $\tilde{\gamma}=0$. Thus, even if $\tilde{\gamma}$ is not sparse in general, it is "sparse" for the control genes. If we leave $\tilde{Z}$ out of the model, RUV-4 may not properly incorporate $\tilde{Z}$ into $W$. This is a strong argument for including $\tilde{Z}$. A second complication is that, in cases in which $p>1$, it is common in practice that the columns of $X$ are in some way "related." For example, several columns of $X$ may simply be dummy variables representing different levels of a single factor. As a result, if $\beta_{l j}$ is non-zero for one value of $l$, we might expect that $\beta_{l^{\prime} j}$ is non-zero for several other values of $l^{\prime}$ as well - even when $\beta$ as a whole is sparse. Thus, the genes for which $\tilde{\beta}$ is non-zero will also tend to be the genes for which $\tilde{\gamma}$ is non-zero. This too may be an argument for including $\tilde{Z}$. On balance, if $p$ is small, it is probably best to include $\tilde{Z}$. Once again, however, the most prudent strategy may simply be to run the analysis both with and without $\tilde{Z}$, and carefully inspect the results.

### 3.6.3 Violation of the control gene assumption

We now consider what happens when certain assumptions are violated. In particular, we will first consider what happens when $\beta_{c} \neq 0$. Later we will consider what happens when $K \neq k$. Suppose $\beta_{c} \neq 0$. By (43) we see that this will result in additional conditional bias to $\hat{b}_{W X}$. The amount of this bias is $\mathbb{E}\left[\beta_{c}\left(\alpha_{c}+\xi_{c}\right)^{\prime}\left[\left(\alpha_{c}+\xi_{c}\right)\left(\alpha_{c}+\xi_{c}\right)^{\prime}\right]^{-1} \mid \alpha_{c}\right]$. In general, depending on $\beta_{c}$ and $\alpha_{c}$, this bias may be arbitrarily bad. However, we observe that if $\beta_{c}^{\prime}$ is approximately orthogonal to $\left(\alpha_{c}+\xi_{c}\right)^{\prime}$ then the bias will be approximately 0 . With high probability $\xi_{c}$ is approximately orthogonal to $\beta_{c}$. Therefore, we should not expect violations of the control gene assumption to be problematic unless $\beta_{c} \alpha_{c}^{\prime}$ is appreciably non-zero.

More formally, suppose $\beta_{c} \alpha_{c}^{\prime}=0$. Then

$$
\begin{align*}
\beta_{c}\left(\alpha_{c}+\xi_{c}\right)^{\prime}\left[\left(\alpha_{c}+\xi_{c}\right)\left(\alpha_{c}+\xi_{c}\right)^{\prime}\right]^{-1} & =\beta_{c} P_{\beta_{c}^{\prime}} \xi_{c}^{\prime}\left[\left(\alpha_{c}+\xi_{c} P_{\beta_{c}^{\prime}}+\xi_{c} R_{\beta_{c}^{\prime}}\right)\left(\alpha_{c}^{\prime}+P_{\beta_{c}^{\prime}} \xi_{c}^{\prime}+R_{\beta_{c}^{\prime}} \xi_{c}^{\prime}\right)\right]^{-1}  \tag{66}\\
& =\beta_{c} P_{\beta_{c}^{\prime}} \xi_{c}^{\prime}\left[\xi_{c} P_{\beta_{c}^{\prime}} P_{\beta_{c}^{\prime}} \xi_{c}^{\prime}+\left(\alpha_{c}+\xi_{c} R_{\beta_{c}^{\prime}}\right)\left(\alpha_{c}^{\prime}+R_{\beta_{c}^{\prime}} \xi_{c}^{\prime}\right)\right]^{-1} \tag{67}
\end{align*}
$$

Now, the joint distribution of $\left(\xi_{c} P_{\beta_{c}^{\prime}}, \xi_{c} R_{\beta_{c}^{\prime}}\right)$ is equal to the joint distribution of $\left(-\xi_{c} P_{\beta_{c}^{\prime}}, \xi_{c} R_{\beta_{c}^{\prime}}\right)$, so

$$
\begin{align*}
& \mathbb{E}\left\{\beta_{c} P_{\beta_{c}^{\prime}} \xi_{c}^{\prime}\left[\xi_{c} P_{\beta_{c}^{\prime}} P_{\beta_{c}^{\prime}} \xi_{c}^{\prime}+\left(\alpha_{c}+\xi_{c} R_{\beta_{c}^{\prime}}\right)\left(\alpha_{c}^{\prime}+R_{\beta_{c}^{\prime}} \xi_{c}^{\prime}\right)\right]^{-1} \mid \alpha_{c}\right\} \\
&=\mathbb{E}\left\{\beta_{c}\left(-P_{\beta_{c}^{\prime}} \xi_{c}^{\prime}\right)\left[\left(-\xi_{c} P_{\beta_{c}^{\prime}}\right)\left(-P_{\beta_{c}^{\prime}} \xi_{c}^{\prime}\right)+\left(\alpha_{c}+\xi_{c} R_{\beta_{c}^{\prime}}\right)\left(\alpha_{c}^{\prime}+R_{\beta_{c}^{\prime}} \xi_{c}^{\prime}\right)\right]^{-1} \mid \alpha_{c}\right\}  \tag{68}\\
&=-\mathbb{E}\left\{\beta_{c} P_{\beta_{c}^{\prime}} \xi_{c}^{\prime}\left[\xi_{c} P_{\beta_{c}^{\prime}} P_{\beta_{c}^{\prime}} \xi_{c}^{\prime}+\left(\alpha_{c}+\xi_{c} R_{\beta_{c}^{\prime}}\right)\left(\alpha_{c}^{\prime}+R_{\beta_{c}^{\prime}} \xi_{c}^{\prime}\right)\right]^{-1} \mid \alpha_{c}\right\} \tag{69}
\end{align*}
$$

and therefore $\mathbb{E}\left\{\beta_{c}\left(\alpha_{c}+\xi_{c}\right)^{\prime}\left[\left(\alpha_{c}+\xi_{c}\right)\left(\alpha_{c}+\xi_{c}\right)^{\prime}\right]^{-1} \mid \alpha_{c}\right\}=0$. No bias is introduced by a breakdown of the control gene assumption in which $\beta_{c} \neq 0$ but $\beta_{c} \alpha_{c}^{\prime}=0$.

### 3.6.4 Misspecification of $k$ : Consequences for $\hat{\beta}$

We now consider what happens when $K \neq k$. There are two possible cases: $K<k$ and $K>k$. First consider the case that $K<k$. We may be tempted to regard $\hat{W}^{(K)}$ as simply a "reduced" version of $\hat{W}^{(k)}$ from which we have dropped $k-K$ columns. In other words, we might guess that $\mathfrak{R}\left(\hat{W}^{(K)}\right) \subset \mathfrak{R}\left(\hat{W}^{(k)}\right)$. Since omitting terms from a regression model generally leads to biased estimates, we might therefore reason that setting $K<k$ will lead to (additional) bias in our estimate of $\beta$. This is only partially correct. Setting $K<k$ does bias $\hat{\beta}$. However, it is not generally true that $\mathfrak{\Re}\left(\hat{W}^{(K)}\right) \subset \mathfrak{R}\left(\hat{W}^{(k)}\right)$. One trivial reason for this is that, depending on our choice of factor analysis routine, it may not even be the case that $\mathfrak{R}\left(\hat{W}_{0}^{(K)}\right) \subset \Re\left(\hat{W}_{0}^{(k)}\right)$. However, suppose that indeed $\mathfrak{R}\left(\hat{W}_{0}{ }^{(K)}\right) \subset \mathfrak{R}\left(\hat{W}_{0}^{(k)}\right)$. It does not follow that $\Re\left(\hat{W}^{(K)}\right) \subset \Re\left(\hat{W}^{(k)}\right)$. Recall that we estimate $b_{W X}$ by regressing $b_{Y_{c} X}$ on $\hat{\alpha}_{c}$. However, the rows of $\hat{\alpha}_{c}$ are not in general orthogonal. Dropping some rows from $\hat{\alpha}_{c}$ therefore leads to a different estimate $b_{W X}$, even for the rows that remain. The conclusion then is that setting $K<k$ biases $\hat{\beta}$, but quantifying the bias is difficult. Nonetheless, by considering the limiting case that $K=0$ (i.e. no adjustment), we may reason that the bias is potentially substantial. The simulations of Section 4 support this conclusion.

We now consider the case that $K>k$. We focus on the "worst case" in which $K=m-1$, but our results are clearly relevant whenever $k<K<m-1$. Note that when $K=m-1$ there is no role for the factor analysis in Step 2; $\hat{W}_{0}^{(m-1)}$ is simply equal to $X_{\perp}$. Let $W_{1} \equiv\left(X \mid W_{0}\right)_{\perp}$. Assume without loss of generality that $\hat{W}_{0}^{(m-1)}=\left(W_{0} \mid W_{1}\right)$. Now define

$$
\begin{align*}
\tilde{W} & \equiv\left(W \mid W_{1}\right)  \tag{70}\\
\tilde{\alpha} & \equiv\binom{\alpha}{0_{m-k-1 \times n}} . \tag{71}
\end{align*}
$$

Observe that $b_{\tilde{W} X}=\left(b_{W X} \mid 0\right)$ and $\tilde{W} \tilde{\alpha}=W \alpha$. We may therefore regard $\tilde{W} \tilde{\alpha}$ as a reparameterization of $W \alpha$. Under this reparameterization, $\hat{W}_{0}^{(m-1)}$ is a perfect estimator of $\tilde{W}_{0}$. Therefore, expressions (38) and (39) apply exactly. To analyze the bias and variance under assumptions (44), (45), and the assumption that $n_{c}$ is large, first define

$$
\tilde{\Psi}^{2} \equiv\left(\begin{array}{cc}
\Psi^{2} & 0_{k \times m-k-1}  \tag{72}\\
0_{m-k-1 \times k} & 0_{m-k-1 \times m-k-1}
\end{array}\right)
$$

By (46)

$$
\begin{align*}
\operatorname{Bias}\left[\hat{\beta}_{j_{\bar{c}}}^{(m-1)} \mid \tilde{\alpha}_{\star j_{\bar{c}}}\right] & \approx b_{\tilde{W} X}\left(\tilde{\Psi}^{2} / \sigma_{0}^{2}+I\right)^{-1} \tilde{\alpha}_{\star j_{\bar{c}}}  \tag{73}\\
& =b_{W X}\left(\Psi^{2} / \sigma_{0}^{2}+I\right)^{-1} \alpha_{\star j_{\bar{c}}}  \tag{74}\\
& \approx \operatorname{Bias}\left[\hat{\beta}_{j_{\bar{c}}}^{(k)} \mid \alpha_{\star j_{\bar{c}}}\right] \tag{75}
\end{align*}
$$

and by (48)

$$
\begin{align*}
\operatorname{Var}\left[\hat{\beta}_{j_{\bar{c}}}^{(m-1)} \mid \tilde{\alpha}_{\star j_{\bar{c}}}\right] & \approx \sigma_{j_{\bar{c}}}^{2}\left(1+b_{\tilde{W} X} \tilde{\Psi}^{4}\left(\tilde{\Psi}^{2}+\sigma_{0}^{2} I\right)^{-2} b_{\tilde{W} X}^{\prime}\right)  \tag{76}\\
& =\sigma_{j_{\bar{c}}}^{2}\left(1+b_{W X} \Psi^{4}\left(\Psi^{2}+\sigma_{0}^{2} I\right)^{-2} b_{W X}^{\prime}\right)  \tag{77}\\
& \approx \operatorname{Var}\left[\hat{\beta}_{j_{\bar{c}}}^{(k)} \mid \alpha_{\star j_{\bar{c}}}\right] . \tag{78}
\end{align*}
$$

Thus, up to approximation, the bias and variance of $\hat{\beta}_{j_{\bar{c}}}^{(m-1)}$ and $\hat{\beta}_{j_{\bar{c}}}^{(k)}$ are the same; nothing is lost by over-estimating $k$. It is useful to recall at this point what approximations are being made that justify this conclusion. The approximations are based on the assumption that $n_{c}$ is large. The approximations may be made arbitrarily good by a sufficiently large $n_{c}$. If $n_{c}$ is not sufficiently large, we may in fact pay a substantial price by overestimating $k$. In particular, $\operatorname{Var}\left[\hat{b}_{W X}\right]$ may no longer be negligible, and the $\sigma_{j_{\bar{c}}}^{2} \operatorname{tr}\left(\operatorname{Var}\left[\hat{b}_{W X}\right]\right)$ and $\alpha_{\star j_{\bar{c}}}^{\prime} \operatorname{Var}\left[\hat{b}_{W X}\right] \alpha_{\star j_{\bar{c}}}$ terms of (39) may become important. We return to this point in Section 3.9.1.

### 3.6.5 Misspecification of $k$ : Consequences for $\hat{\sigma}^{2}$

In practice, estimating $\sigma^{2}$ is much more complicated than Section 3.6.1 suggests. The difficulty arises in the estimation of $k$. The performance of $\hat{\sigma}_{j}^{2}$ depends critically on a proper estimation of $k$. Unlike $\hat{\beta}_{j}, \hat{\sigma}_{j}^{2}$ performs poorly both when $k$ has been underestimated and when $k$ has been overestimated. Therefore we cannot simply dodge the issue by systematically over- or underestimating $k$ as we can with $\hat{\beta}$.

We will not analyze the statistical properties of $\hat{\sigma}_{j}^{2}$ in any detail. Roughly speaking, however, we may summarize the main issues as follows: Firstly, overestimating $k$ increases the variance of $\hat{\sigma}^{2}$. This is simply because $\sigma^{2}$ must be estimated using fewer degrees of freedom. Moreover, overestimating $k$ biases $\hat{\sigma}^{2}$ downwards on average. This is because the factor analysis routine in Step 2 will presumably allocate the extra $K-k$ dimensions of $\hat{W}_{0}$ to the (random) dimensions in which $\epsilon$ shows the greatest variation. The residuals will therefore be too small. Finally, underestimating $k$ biases $\hat{\sigma}^{2}$ upwards on average, possibly substantially. This is because some terms of $W \alpha$ are not effectively adjusted away. Some unwanted variation remains in the residuals, and this inflates $\hat{\sigma}^{2}$.

To see that underestimating $k$ biases $\hat{\sigma}^{2}$ upwards on average and overestimating $k$ biases $\hat{\sigma}^{2}$ downwards on average it is helpful to consider the specific case in which we use the singular value decomposition (SVD) as our factor analysis method. Let $U D V^{\prime}$ be the singular value decomposition of $R_{X} Y$, i.e. $R_{X} Y=U D V^{\prime}$ where $U$ and $V$ are orthonormal matrices and $D$ is a diagonal matrix with decreasing diagonal entries denoted by $d_{i}$. $\hat{W}_{0}^{(K)}$ is defined to be the first $K$ columns of $U$. Let $\bar{\sigma}^{2} \equiv \sum_{j=1}^{n} \sigma_{j}^{2}$ denote the average gene variance. Let $\dot{\sigma}^{2} \equiv \sum_{j=1}^{n} \hat{\sigma}_{j}^{2}$ denote the estimated average variance. The estimated average variance as a function of $K$ is therefore

$$
\begin{align*}
\left(\dot{\sigma}^{2}\right)^{(K)} & =\frac{1}{n} \sum_{j=1}^{n}\left(\hat{\sigma}_{j}^{2}\right)^{(K)}  \tag{79}\\
& =\frac{1}{n} \sum_{j=1}^{n} \frac{1}{m-K-1}\left(R_{\left(X \mid \hat{W}_{0}^{(K)}\right)} Y_{\star j}\right)^{\prime}\left(R_{\left(X \mid \hat{W}_{0}^{(K)}\right)} Y_{\star j}\right)  \tag{80}\\
& =\frac{1}{n(m-K-1)} \sum_{j=1}^{n}\left(R_{\hat{W}_{0}^{(K)}} R_{X} Y_{\star j}\right)^{\prime}\left(R_{\hat{W}_{0}^{(K)}} R_{X} Y_{\star j}\right)  \tag{81}\\
& =\frac{1}{n(m-K-1)} \sum_{j=1}^{n} V_{j \star} D U^{\prime} R_{\hat{W}_{0}^{(K)}} U D V_{j \star}^{\prime}  \tag{82}\\
& =\frac{1}{n(m-K-1)} \sum_{j=1}^{n} \sum_{i=K+1}^{m} V_{j i}^{2} d_{i}^{2}  \tag{83}\\
& =\frac{1}{n(m-K-1)} \sum_{i=K+1}^{m} d_{i}^{2} . \tag{84}
\end{align*}
$$

Thus $\left(\dot{\sigma}^{2}\right)^{(K)}$ is decreasing in $K$, since the $d_{i}$ are decreasing in $i$. Since $\dot{\sigma}^{2}$ is an unbiased estimator of $\bar{\sigma}^{2}$ when $\hat{W}_{0}=W_{0}$, it follows that if $\hat{W}_{0}^{(k)}=W_{0},\left(\dot{\sigma}^{2}\right)^{(K)}$ will be biased upwards when $K<k$ and biased downwards when $K>k$. Of course, in practice, it is not true that $\hat{W}_{0}^{(k)}=W_{0}$ but rather that $\hat{W}_{0}^{(k)} \approx W_{0}$,
so these results hold only approximately. A full discussion is beyond the scope of this paper. Nonetheless, we do feel that the above argument is useful for the intuition it provides. Moreover, in both simulation experiments and the analysis of real data, we have found that the conclusions tend to hold - when $K$ is too large, $\hat{\sigma}^{2}$ is too small; when $K$ is too small, $\hat{\sigma}^{2}$ is too large.

### 3.6.6 Estimating $k$

As Sections 3.6.4 and 3.6.4 suggest, a good choice of $K$ is critical to the performance of RUV-4. Unfortunately, selecting an appropriate $K$ is difficult. It is not even clear that the optimal $K$ for $\hat{\beta}$ is the same as the optimal $K$ for $\hat{\sigma}^{2}$. (Indeed, we have had success estimating $\hat{\beta}$ and $\hat{\sigma}^{2}$ using different values of $K$, but we do not discuss this approach in this paper.)

As with RUV-2, we feel the best way to select $K$ for RUV-4 is to run the analysis for several values of $K$ and choose the "best" one based on $p$-value histograms, RLE plots, the rankings of positive controls, and other quality assessments Gagnon-Bartsch and Speed (2012). We are unaware of any good algorithmic way to estimate $k$, and we feel there is an important role for human judgment.

Nonetheless, this hands-on approach is not always feasible or desirable. For example, in Section 4 we present the results of simulation experiments in which RUV-4 was run thousands of times. Estimating $k$ "by hand" thousands of times is not feasible. Therefore we will now present a method to estimate $k$ that we have found to perform moderately well in many situations.

Our method for estimating $k$ relies on control genes. The key insight is that if RUV-4 works as intended

$$
\begin{equation*}
\mathbb{E}\left[\hat{\beta}_{c} \mid \alpha\right] \approx 0 \tag{85}
\end{equation*}
$$

and thus

$$
\begin{equation*}
\hat{\beta}_{j_{c}}^{2} \quad \dot{\sim} \quad \operatorname{Var}\left[\hat{\beta}_{j_{c}} \mid \alpha\right] \chi_{1}^{2} \tag{86}
\end{equation*}
$$

The symbol $\dot{\sim}$ means "is approximately distributed as." Unfortunately, the quantity Var $\left[\hat{\beta}_{j_{c}} \mid \alpha\right]$ is difficult to analyze. We therefore begin by considering a gene $j_{0}$ that is not a designated control gene but nonetheless such that $\beta_{j_{0}}=0$.

Assume (44), (45), and that $n_{c}$ is large. Assume that RUV-4 works as intended so that $\mathbb{E}\left[\hat{\beta}_{j_{0}} \mid \alpha\right] \approx 0$. By (62)

$$
\begin{equation*}
\operatorname{Var}\left[\hat{\beta}_{j_{0}} \mid \alpha\right] \approx \sigma_{j_{0}}^{2}\left(1+\hat{b}_{W X} \hat{b}_{W X}^{\prime}\right) \tag{87}
\end{equation*}
$$

and therefore

$$
\begin{equation*}
s_{j_{0}}^{2} \equiv \frac{\hat{\beta}_{j_{0}}^{2}}{1+\hat{b}_{W X} \hat{b}_{W X}^{\prime}} \quad \dot{\sim} \quad \sigma_{j_{0}}^{2} \chi_{1}^{2} \tag{88}
\end{equation*}
$$

As in Section (3.6.4), suppose that $\hat{W}_{0}^{(m-1)}=\left(W_{0} \mid W_{1}\right)$. Assume that $W_{1}$, while otherwise arbitrary, is fixed. Then for all $i$ such that $k<i<m$ and all $j$ such that $1 \leq j \leq n$,

$$
\begin{equation*}
s_{i j}^{2} \equiv\left(\hat{\alpha}_{i j}^{(m-1)}\right)^{2} \sim \sigma_{j}^{2} \chi_{1}^{2} \tag{89}
\end{equation*}
$$

Now, for $1 \leq i<m$ consider the quantity

$$
\begin{equation*}
r_{i}^{(0)} \equiv \operatorname{median}_{j_{0}} \sqrt{s_{i j_{0}}^{2} / s_{j_{0}}^{2}} . \tag{90}
\end{equation*}
$$

This quantity gives some measure of the scale of the $i^{\text {th }}$ row of $\hat{\alpha}^{(m-1)}$ relative to the scale of $\epsilon$. In light of (88) and (89), we would expect that $r_{i}^{(0)} \approx 1$ for $k<i<m$. We can exploit this fact to estimate $k$. For example, we could estimate $k$ by $\#\left\{r_{i}^{(0)}>C\right\}$, where $C>1$ is some cutoff value.

In practice, we will want to designate every gene known to be uninfluenced by $X$ as a control gene. Thus we should not expect to have available any genes $j_{0}$ as described above. Instead, we will just use the control genes. However, the statistical properties of the control genes are different than the statistical properties of the other genes. In particular, since we estimate $b_{W X}$ by regressing $b_{Y_{c} X}$ on $\hat{\alpha}_{c}$, it is not true that $\hat{b}_{W X}$ is independent of $\zeta_{j_{c}}$ and $\xi_{\star j_{c}}$. The practical consequence of this is that $\hat{b}_{W X}$ is overfitted to the control genes, and as a result the variance of $\hat{\beta}_{j_{c}}$ tends to be somewhat less than $\sigma_{j_{c}}^{2}\left(1+\hat{b}_{W X} \hat{b}_{W X}^{\prime}\right)$. Note that $\hat{\beta}_{c}$ may be regarded as the residuals of a regression of $b_{Y_{c} X}$ on $\hat{\alpha}_{c}$. In a "standard" regression, the residuals are "too small" by a factor of $\sqrt{(N-P) / N}$, where $N$ is the number of observations and $P$ is the number of regressors. This inspires us to define:

$$
\begin{equation*}
r_{i} \equiv \operatorname{median}_{j_{c}} \sqrt{\left(\frac{n_{c}-K_{0}}{n_{c}}\right) \frac{s_{i j_{c}}^{2}}{s_{j_{c}}^{2}}} \tag{91}
\end{equation*}
$$

where $s_{j_{c}}^{2}$ is defined analogously to (88), and where $K_{0}$ is the value of $K$ used in the calculation of $s_{j_{c}}^{2} \cdot{ }^{2}$ This is somewhat ad hoc. The regression of $b_{Y_{c} X}$ on $\hat{\alpha}_{c}$ is not a "standard" regression. In particular, we have ignored the fact that different genes have different variances. Nonetheless, we now define our estimate of $k$ as

$$
\begin{equation*}
\hat{k}(C) \equiv \#\left\{r_{i}>C\right\} \tag{92}
\end{equation*}
$$

We must choose a value for $C$. In choosing a value for $C$ we consider the fact that it is not actually true that $\hat{W}_{0}^{(m-1)}=\left(W_{0} \mid W_{1}\right)$ where $W_{1}$ is some arbitrary but fixed matrix. In particular, we may not take $W_{1}$ to be fixed. Its parameterization is random, and determined by the factor analysis routine in Step 2 of RUV-4. This did not matter in Section 3.6.4 because the parameterization of $\hat{W}_{0}$ was irrelevant. Here, however, the parameterization of $\hat{W}_{0}$ does matter; $r_{i}$ is defined in terms of the individual columns of $\hat{W}_{0}$. Assume that we use the SVD as the method of factor analysis in Step 2 of RUV-4. In this case, we might expect that $\hat{W}_{0}^{(k)} \approx W_{0}$. Again, this is only approximately correct, and a full discussion is beyond the scope of this paper. For sake of argument, however, simply assume that $\hat{W}_{0}^{(k)}=W_{0}$. We may then write $\hat{W}_{0}^{(m-1)}=\left(W_{0} \mid \tilde{W}_{1}\right)$, implicitly defining $\tilde{W}_{1}$. The problem is that $\tilde{W}_{1}$ is not fixed; it has been rotated so that the most variation is captured by first column. As a result, we should not expect that $r_{k+1} \approx 1$ but rather that $r_{k+1}>1$. To fix this problem, we set $C>1$. We choose to set $C=\mathbb{E}(\eta)$ where $\eta$ is the principal singular value of an $m \times n$ matrix of independent $\mathrm{N}\left(0, \frac{1}{n}\right)$ random variables. In the analyses of this paper we simply approximate $C$ by simulation. A far more computationally efficient approach would be to approximate $C$ using the fact that the distribution of $\eta^{2}$ is approximately Tracy-Widom. This approximation can be very good. See, for example, Ma (2012).

### 3.7 The Inverse Method

In Section 3.6 .4 we saw that overestimating $k$ does not seriously degrade the performance of $\hat{\beta}$ as long as a sufficient number of control genes are available. In Section 3.6.5 we saw that overestimating (or underestimating) $k$ does seriously degrade the performance of $\hat{\sigma}^{2}$. We are left with a dilemma. A good estimate of $\beta$ is readily available - just set $K$ as high as it can go, to $m-1$ - but we are unable to estimate $\sigma^{2}$. To solve this dilemma we will introduce a novel method for estimating $\sigma^{2}$, which we name the "inverse method." We introduce the abstract method in Section 3.7.1. In Section 3.7 .2 we apply the inverse method to RUV-4. In Sections 3.7.3 and 3.7.5 we reformulate our estimators. These reformulations are of both theoretical and practical interest. We provide discussions in Sections 3.7.4 and 3.7.6.

### 3.7.1 The Inverse Method

We now present the inverse method in the abstract, followed by a simple example. The method is so simple as to seem trivial. However, as we will eventually see, properly applied it can be quite powerful. Note that

[^2]all of the notation used in this section is specific to this section only.
Let $\hat{\theta}_{U}$ be a family of estimators indexed by $U$. What $\hat{\theta}_{U}$ estimates need not be relevant. Assume that there exist some (possibly random) values of $U$, denoted $U_{1}, U_{2}, \ldots, U_{i}, \ldots$, such that
\[

$$
\begin{equation*}
\mathbb{E}\left[\hat{\theta}_{U_{i}} \mid U_{i}\right]=0 \tag{93}
\end{equation*}
$$

\]

Assume also that

$$
\begin{equation*}
\operatorname{Var}\left[\hat{\theta}_{U_{i}} \mid U_{i}\right]=f_{U_{i}}\left(\sigma^{2}\right) \tag{94}
\end{equation*}
$$

where $\sigma^{2}$ is some unknown parameter and $f_{U_{i}}$ is some function. Combining (93) and (94) gives

$$
\begin{equation*}
\mathbb{E}\left[\hat{\theta}_{U_{i}}^{2} \mid U_{i}\right]=f_{U_{i}}\left(\sigma^{2}\right) \tag{95}
\end{equation*}
$$

If the $f_{U_{i}}$ are linear functions of $\sigma^{2}$, then

$$
\begin{align*}
& f_{U_{i}}^{-1}\left(\mathbb{E}\left[\hat{\theta}_{U_{i}}^{2} \mid U_{i}\right]\right)=\sigma^{2}  \tag{96}\\
& \mathbb{E}\left[f_{U_{i}}^{-1}\left(\hat{\theta}_{U_{i}}^{2}\right) \mid U_{i}\right]=\sigma^{2} \tag{97}
\end{align*}
$$

where $f_{U_{i}}^{-1}$ is the functional inverse of $f_{U_{i}}$.
If such $U_{i}$ are available, if the functions $f_{U_{i}}$ are known, and if we have the data necessary to compute $\hat{\theta}_{U_{i}}$, we are able to compute $f_{U_{i}}^{-1}\left(\hat{\theta}_{U_{i}}^{2}\right)$. We may regard each of these $f_{U_{i}}^{-1}\left(\hat{\theta}_{U_{i}}^{2}\right)$ as estimates of $\sigma^{2}$. We may then combine the $f_{U_{i}}^{-1}\left(\hat{\theta}_{U_{i}}^{2}\right)$ in some way, e.g. take their average, to produce a final "inverse" estimate of $\sigma^{2}$.

For concreteness, we will now present a very simple (but contrived) example. Suppose we have a standard linear regression model

$$
\begin{equation*}
Y_{n \times 1}=X_{n \times p} \beta_{p \times 1}+\epsilon_{n \times 1} \tag{98}
\end{equation*}
$$

where $Y$ is observed, $X$ is fixed and observed, $\beta$ is fixed and unknown, $p<n$, and the elements of $\epsilon$ are IID with expectation 0 and variance $\sigma^{2}$. To estimate $\sigma^{2}$ using the inverse method, first note that we may model $Y$ as

$$
\begin{equation*}
Y=X \beta+U \theta+\epsilon \tag{99}
\end{equation*}
$$

where $U$ may be any $n \times 1$ matrix and $\theta=0$. If $U$ is not a linear combination of $X$, then we may estimate $\theta$ by OLS and let

$$
\hat{\theta}_{U} \equiv\left(U^{\prime} R_{X} U\right)^{-1} U^{\prime} R_{X} Y
$$

Let $U_{1}, U_{2}, \ldots, U_{i}, \ldots$ be random matrices whose entries are IID standard normal and independent of $\epsilon$. Then with probability $1, U_{i}$ is not a linear combination of the columns of $X$ and $\hat{\theta}_{U_{i}}$ exists. Moreover,

$$
\begin{align*}
\mathbb{E}\left[\hat{\theta}_{U_{i}} \mid U_{i}\right] & =0  \tag{100}\\
\operatorname{Var}\left[\hat{\theta}_{U_{i}} \mid U_{i}\right] & =\sigma^{2}\left(U_{i}^{\prime} R_{X} U_{i}\right)^{-1} \tag{101}
\end{align*}
$$

and therefore

$$
\begin{equation*}
\mathbb{E}\left[\left.\frac{\hat{\theta}_{U_{i}}^{2}}{\left(U_{i}^{\prime} R_{X} U_{i}\right)^{-1}} \right\rvert\, U_{i}\right]=\sigma^{2} \tag{102}
\end{equation*}
$$

Thus, we might imagine generating many $U_{i}$, and for each $U_{i}$ calculating $\hat{\theta}_{U_{i}}^{2} /\left(U_{i}^{\prime} R_{X} U_{i}\right)^{-1}$, and then averaging these values to produce an estimate of $\sigma^{2}$. Or, by taking the limit of this process, we may define the inverse estimator of $\sigma^{2}$ to be

$$
\begin{equation*}
\hat{\sigma}_{\text {inv }}^{2} \equiv \mathbb{E}_{U_{1}}\left[\frac{\hat{\theta}_{U_{1}}^{2}}{\left(U_{1}^{\prime} R_{X} U_{1}\right)^{-1}}\right] \tag{103}
\end{equation*}
$$

Note that, defined this way, it is actually the case that

$$
\begin{equation*}
\hat{\sigma}_{\mathrm{inv}}^{2}=\frac{1}{n-p}(Y-X \hat{\beta})^{\prime}(Y-X \hat{\beta}) \tag{104}
\end{equation*}
$$

and $\hat{\sigma}_{\text {inv }}^{2}$ is thus equivalent to the standard OLS estimate of $\sigma^{2}$ (proof omitted).

### 3.7.2 The Inverse Method for RUV-4

We now apply the inverse method to RUV-4. Let $X^{\star}$ be a random "factor of interest" chosen uniformly at random from the unit $(m-1)$-sphere. Since $X^{\star}$ is random, it should not be "truly associated" with the expression levels of any of the genes. We may model $Y$ as

$$
\begin{equation*}
Y=X \beta+W \alpha+X^{\star} \beta^{\star}+\epsilon \tag{105}
\end{equation*}
$$

where $\beta^{\star}=0$. We will estimate $\beta^{\star}$ by RUV-4. In this context, $X$ is now an unwanted factor and plays the role of $Z$. In Section 3.6 .2 we discussed two ways to handle a known covariate: ignore it and let RUV-4 incorporate it into $W$, or explicitly adjust for it. In this case, it is almost certainly better to explicitly adjust for $X$. By assumption, the control genes are uninfluenced by $X$, and therefore RUV-4 will not properly incorporate $X$ into $W . \hat{\beta}^{\star}$ may be biased, violating the key assumption of the inverse method (see (112), below).

Therefore, we explicitly adjust for $X$. Define $U$ to be the matrix whose columns are the first $m-1$ eigenvectors of $R_{X} Y_{c} Y_{c}^{\prime} R_{X}$. Note that U is a specific parameterization of $X_{\perp}$. This parameterization will prove convenient in Section 3.7.5. Now define:

$$
\begin{align*}
\mathrm{Y} & \equiv \mathrm{U}^{\prime} Y  \tag{106}\\
\mathrm{X} & \equiv \mathrm{U}^{\prime} X^{\star}  \tag{107}\\
\mathrm{W} & \equiv \mathrm{U}^{\prime} W  \tag{108}\\
\varepsilon & \equiv \mathrm{U}^{\prime} \epsilon  \tag{109}\\
\mathrm{m} & \equiv m-1 \tag{110}
\end{align*}
$$

Note that:

$$
\begin{equation*}
\mathrm{Y}_{\mathrm{m} \times n}=\mathrm{X}_{\mathrm{m} \times 1} \beta_{n \times 1}^{\star}+\mathrm{W}_{\mathrm{m} \times k} \alpha_{k \times n}+\varepsilon_{\mathrm{m} \times n} \tag{111}
\end{equation*}
$$

Let $\hat{\beta}^{\star}$ denote the RUV-4 estimator of $\beta^{\star}$ for some fixed $K$. Typically we set $K=\mathrm{m}-1$.
We now state the key assumption of the inverse method applied to RUV-4. We assume that with high probability

$$
\begin{equation*}
\mathbb{E}\left[\hat{\beta}^{\star} \mid X\right] \approx 0 \tag{112}
\end{equation*}
$$

The real assumption here is that RUV-4 "works" - that the unwanted variation is effectively adjusted for, and that the regression coefficients corresponding to a random "factor of interest" that is not truly associated with the expression levels of any genes will in fact be estimated to be about 0 .

If $n_{c}$ is large, we have by (62) that

$$
\begin{equation*}
\operatorname{Var}\left[\hat{\beta}_{j_{\bar{c}}}^{\star} \mid \mathrm{X}\right] \approx \sigma_{j_{\bar{c}}}^{2}\left(1+\hat{b}_{\mathrm{WX}} \hat{b}_{\mathrm{WX}}^{\prime}\right) . \tag{113}
\end{equation*}
$$

Following the example of the previous section, we define

$$
\begin{equation*}
\left(\hat{\sigma}_{j_{\bar{c}}}^{2}\right)^{(K, \text { inv })} \equiv \mathbb{E}_{\mathrm{X}}\left[\frac{\left(\hat{\beta}_{j_{\bar{c}}}^{\star}\right)^{2}}{1+\hat{b}_{\mathrm{WX}} \hat{b}_{\mathrm{WX}}^{\prime}}\right] \tag{114}
\end{equation*}
$$

In Section 3.7 .5 we will develop an exact analytic expression for $\left(\hat{\sigma}_{j_{\bar{c}}}^{2}\right)^{(K, \text { inv })}$ in the special case that $K=\mathrm{m}-1$. However, it is also very straight-forward to approximate $\left(\hat{\sigma}_{j_{\bar{c}}}^{2}\right)^{(K, \text { inv })}$ more generally by repeatedly generating random $X=U^{\prime} X^{\star}$, fitting with RUV-4, calculating $\left(\hat{\beta}_{j_{\bar{c}}}^{\star}\right)^{2} /\left(1+\hat{b}_{W x} \hat{b}_{W X}^{\prime}\right)$, and averaging the results.

We conclude this section by reiterating the importance of explicitly adjusting for $X$ when calculating $\hat{\beta}^{\star}$. Suppose we do not explicitly adjust for $X$ and RUV-4 does not properly incorporate $X$ into $W$; $X$ is thus simply unadjusted for. As a result, $\hat{\beta}_{j_{\bar{c}}}^{\star}$ will be biased. $\left(\hat{\beta}_{j_{\bar{c}}}^{\star}\right)^{2}$ will be too large and $\left(\hat{\sigma}_{j_{\bar{c}}}^{2}\right)^{(K, \text { inv })}$ will be inflated. To see this more clearly, we present an analogy. In the simple example of Section 3.7 .1 we estimate $\theta$ by $\left(U^{\prime} R_{X} U\right)^{-1} U^{\prime} R_{X} Y$; we "explicitly adjust for $X$." The resulting inverse-method estimate $\hat{\sigma}^{2}$ is $[1 /(n-p)](Y-X \hat{\beta})^{\prime}(Y-X \hat{\beta})$, and $\mathbb{E}\left[\hat{\sigma}^{2}\right]=\sigma^{2}$. Now suppose that we had not explicitly adjusted for $X$, but instead had estimated $\theta$ by $\left(U^{\prime} U\right)^{-1} U^{\prime} Y$. The resulting inverse-method estimate $\hat{\sigma}^{2}$ would be $(1 / n) Y^{\prime} Y$. The expected value of $\hat{\sigma}^{2}$ would be

$$
\beta^{\prime}\left(\frac{X^{\prime} X}{n}\right) \beta+\sigma^{2}
$$

Thus, by not explicitly adjusting for $X$, we would inflate our estimate of $\sigma^{2}$ by a factor of roughly

$$
1+\frac{\beta^{\prime} X^{\prime} X \beta}{n \sigma^{2}}
$$

### 3.7.3 A Closed-Form Solution for $\hat{\beta}^{(R U V-i n v)}$

Define $\hat{\beta}^{(\text {RUV -inv) }}$ to be the RUV-4 estimator when $K=m-1$. Note that the notation is slightly misleading, since strictly speaking the inverse method is a method for estimating variances, and can be applied to a wide class of estimators, including RUV-4 for any $K$. However, the RUV-4 estimator with $K=m-1$ is the preferred estimator to which we apply the inverse method - and indeed the estimator which most requires and initially inspired the method - and hence we denote it by $\hat{\beta}^{(R U V-i n v)}$. The goal of this section is to
produce a closed-form expression for $\hat{\beta}^{(\text {RUV }-i n v)}$. We begin by reformulating the four-step estimator:

$$
\begin{align*}
\hat{\beta}^{(\mathrm{RUV}-4)} & =X^{\prime}(Y-\hat{W} \hat{\alpha})  \tag{115}\\
& =X^{\prime}\left[Y-\left(\hat{W}_{0}+X b_{Y_{c} X} \hat{\alpha}_{c}^{\prime}\left(\hat{\alpha}_{c} \hat{\alpha}_{c}^{\prime}\right)^{-1}\right) \hat{\alpha}\right]  \tag{116}\\
& =X^{\prime} Y-b_{Y_{c} X} \hat{\alpha}_{c}^{\prime}\left(\hat{\alpha}_{c} \hat{\alpha}_{c}^{\prime}\right)^{-1} \hat{\alpha}  \tag{117}\\
& =X^{\prime} Y-X^{\prime} Y_{c} Y_{c}^{\prime} \hat{W}_{0}\left(\hat{W}_{0}^{\prime} Y_{c} Y_{c}^{\prime} \hat{W}_{0}\right)^{-1} \hat{W}_{0}^{\prime} Y  \tag{118}\\
& =X^{\prime}\left[I-Y_{c} Y_{c}^{\prime} \hat{W}_{0}\left(\hat{W}_{0}^{\prime} Y_{c} Y_{c}^{\prime} \hat{W}_{0}\right)^{-1} \hat{W}_{0}^{\prime}\right] Y  \tag{119}\\
& =X^{\prime}\left(Y_{c} Y_{c}^{\prime}\right)^{\frac{1}{2}}\left[I-\left(Y_{c} Y_{c}^{\prime}\right)^{\frac{1}{2}} \hat{W}_{0}\left(\hat{W}_{0}^{\prime} Y_{c} Y_{c}^{\prime} \hat{W}_{0}\right)^{-1} \hat{W}_{0}^{\prime}\left(Y_{c} Y_{c}^{\prime}\right)^{\frac{1}{2}}\right]\left(Y_{c} Y_{c}^{\prime}\right)^{-\frac{1}{2}} Y  \tag{120}\\
& =X^{\prime}\left(Y_{c} Y_{c}^{\prime}\right)^{\frac{1}{2}} R_{\left(Y_{c} Y_{c}^{\prime}\right)^{\frac{1}{2}} \hat{W}_{0}}\left(Y_{c} Y_{c}^{\prime}\right)^{-\frac{1}{2}} Y  \tag{121}\\
& =X^{\prime}\left(Y_{c} Y_{c}^{\prime}\right)^{\frac{1}{2}} P_{\left(Y_{c} Y_{c}^{\prime}\right)^{-\frac{1}{2}} \hat{W}_{0 \perp}}\left(Y_{c} Y_{c}^{\prime}\right)^{-\frac{1}{2}} Y  \tag{122}\\
& =X^{\prime}\left(Y_{c} Y_{c}^{\prime}\right)^{\frac{1}{2}}\left[\left(Y_{c} Y_{c}^{\prime}\right)^{-\frac{1}{2}} \hat{W}_{0 \perp}\left(\hat{W}_{0 \perp}^{\prime}\left(Y_{c} Y_{c}^{\prime}\right)^{-1} \hat{W}_{0 \perp}\right)^{-1} \hat{W}_{0 \perp}^{\prime}\left(Y_{c} Y_{c}^{\prime}\right)^{-\frac{1}{2}}\right]\left(Y_{c} Y_{c}^{\prime}\right)^{-\frac{1}{2}} Y  \tag{123}\\
& =X^{\prime} \hat{W}_{0 \perp}\left(\hat{W}_{0 \perp}^{\prime}\left(Y_{c} Y_{c}^{\prime}\right)^{-1} \hat{W}_{0 \perp}\right)^{-1} \hat{W}_{0 \perp}^{\prime}\left(Y_{c} Y_{c}^{\prime}\right)^{-1} Y . \tag{124}
\end{align*}
$$

If we now set $K=m-1$ so that $\hat{W}_{0}=X_{\perp}$ and thus $\hat{W}_{0 \perp}=X$, then (124) becomes

$$
\begin{equation*}
\hat{\beta}^{(\mathrm{RUV}-\mathrm{inv})}=\left(X^{\prime}\left(Y_{c} Y_{c}^{\prime}\right)^{-1} X\right)^{-1} X^{\prime}\left(Y_{c} Y_{c}^{\prime}\right)^{-1} Y \tag{125}
\end{equation*}
$$

Again note that although we give the inverse estimator a special name and are able to define it using a relatively simple, closed form expression, it is still exactly equivalent to the RUV-4 estimator with $K=m-1$.
3.7.4 Discussion: $\hat{\beta}^{(R U V-i n v)}$
$\hat{\beta}^{(\text {RUV }}$-inv) is of considerable theoretical interest. It has the form of a GLS estimator. Consider the case in which $\alpha$ is random. Let $\Sigma \equiv \operatorname{Cov}\left[W \alpha_{\star j}\right]$ and let $\delta \equiv W \alpha+\epsilon$. We then have

$$
\begin{equation*}
Y_{\star j}=X \beta_{1 j}+\delta_{\star j} \tag{126}
\end{equation*}
$$

with

$$
\begin{equation*}
\Sigma_{j} \equiv \operatorname{Cov}\left[\delta_{\star j}\right]=\Sigma+\sigma_{j}^{2} I \tag{127}
\end{equation*}
$$

We may therefore wish to regard $\hat{\beta}^{(\text {RUV -inv) }}$ as a GLS estimator of $\beta$ in which $\Sigma_{j}$ has been (implicitly) approximated by $\frac{1}{n_{c}}\left(Y_{c} Y_{c}^{\prime}\right)$. Now,

$$
\begin{align*}
\mathbb{E}\left[\frac{1}{n_{c}}\left(Y_{c} Y_{c}^{\prime}\right)\right] & =\frac{1}{n_{c}} \sum_{j_{c}} \mathbb{E}\left[Y_{\star j_{c}} Y_{\star j_{c}}^{\prime}\right]  \tag{128}\\
& =\frac{1}{n_{c}} \sum_{j_{c}} \mathbb{E}\left[\delta_{\star j_{c}} \delta_{\star j_{c}}^{\prime}\right]  \tag{129}\\
& =\frac{1}{n_{c}} \sum_{j_{c}} \Sigma+\sigma_{j_{c}}^{2} I  \tag{130}\\
& =\Sigma+\bar{\sigma}_{c}^{2} I \tag{131}
\end{align*}
$$

where

$$
\begin{equation*}
\bar{\sigma}_{c}^{2} \equiv \frac{1}{n_{c}} \sum_{j_{c}} \sigma_{j_{c}}^{2} \tag{132}
\end{equation*}
$$

Therefore

$$
\begin{equation*}
\Sigma_{j}=\mathbb{E}\left[\frac{1}{n_{c}}\left(Y_{c} Y_{c}^{\prime}\right)\right]+\left(\sigma_{j}^{2}-\bar{\sigma}_{c}^{2}\right) I \tag{133}
\end{equation*}
$$

and $\frac{1}{n_{c}}\left(Y_{c} Y_{c}^{\prime}\right)$ is a biased estimate of $\Sigma_{j}$, with bias $\left(\bar{\sigma}_{c}^{2}-\sigma_{j}^{2}\right) I$. To some extent, this complicates the interpretation of $\hat{\beta}^{(\text {RUV-inv })}$ as a GLS estimator. $\hat{\beta}^{(\text {RUV-inv })}$ is not the "best" estimator for any specific gene. However, if the values of $\sigma_{j}^{2}$ do not vary wildly from gene to gene and $\bar{\sigma}_{c}^{2} \approx \bar{\sigma}^{2}$ then we may wish to regard $\hat{\beta}^{(R U V-i n v)}$ as a GLS-like estimator that is "reasonably good on average."

In light of (133) we may be tempted to refine our estimator of $\beta$ on a gene-by-gene basis. For example, if initial estimates $\hat{\sigma}_{j}^{2}$ of $\sigma_{j}^{2}$ and $\dot{\sigma}_{c}^{2}$ of $\bar{\sigma}_{c}^{2}$ are available, we may be tempted to estimate $\beta_{j}$ by

$$
\left\{X^{\prime}\left[Y_{c} Y_{c}^{\prime}+n_{c}\left(\hat{\sigma}_{j}^{2}-\dot{\sigma}_{c}^{2}\right) I\right]^{-1} X\right\}^{-1} X^{\prime}\left[Y_{c} Y_{c}^{\prime}+n_{c}\left(\hat{\sigma}_{j}^{2}-\dot{\sigma}_{c}^{2}\right) I\right]^{-1} Y_{\star j}
$$

This is not necessarily a good idea, and may very well prove disastrous. In Section A. 3 of the SM we discuss this issue a bit further. To summarize Section A.3, it may be possible to make use of initial estimates of $\sigma_{j}^{2}$ and $\bar{\sigma}_{c}^{2}$ to refine our estimator of $\beta$ on a gene-by-gene basis, but to do so requires considerable care, and is beyond the scope of this paper. In any case, any gain in performance is likely to be minor, and the performance of the "unrefined" estimator $\hat{\beta}^{(\mathrm{RUV}-\mathrm{inv})}$ is generally adequate.

Finally, we note that the GLS interpretation is not unique to $\hat{\beta}^{\text {(RUV-inv) }}$. From (124) we see that, after an appropriate transformation of the data and some additional algebra (omitted), the RUV-4 estimator may be viewed as a GLS-like estimator for any $K$, not just $K=m-1$. More specifically, if we let $\tilde{Y} \equiv P_{\left(x \mid \hat{W}_{0}\right)} Y$ it can be shown that

$$
\begin{equation*}
\hat{\beta}^{(\mathrm{RUV}-4)}=\left(X^{\prime}\left(\tilde{Y}_{c} \tilde{Y}_{c}^{\prime}\right)^{+} X\right)^{-1} X^{\prime}\left(\tilde{Y}_{c} \tilde{Y}_{c}^{\prime}\right)^{+} \tilde{Y} \tag{134}
\end{equation*}
$$

Note that we must use the generalized inverse $\left(\tilde{Y}_{c} \tilde{Y}_{c}^{\prime}\right)^{+}$because $\tilde{Y}_{c} \tilde{Y}_{c}^{\prime}$ is only rank $K+1$. Alternatively, we may redefine $\tilde{Y}$ as $\left(X \mid \hat{W}_{0}\right)^{\prime} Y$ and let $\tilde{X} \equiv\left(X \mid \hat{W}_{0}\right)^{\prime} X$. The RUV-4 estimator can then be expressed as

$$
\begin{equation*}
\hat{\beta}^{(\mathrm{RUV}-4)}=\left(\tilde{X}^{\prime}\left(\tilde{Y}_{c} \tilde{Y}_{c}^{\prime}\right)^{-1} \tilde{X}\right)^{-1} \tilde{X}^{\prime}\left(\tilde{Y}_{c} \tilde{Y}_{c}^{\prime}\right)^{-1} \tilde{Y} \tag{135}
\end{equation*}
$$

In either case, we may informally describe the approach as throwing away the dimensions spanned by $\left(X \mid \hat{W}_{0}\right)_{\perp}$ and fitting by GLS in the remaining $K+1$ dimensions. If the dimensions spanned by $\left(X \hat{W}_{0}\right)_{\perp}$ only contain noise, removing them should reduce the variance of $\hat{\beta}$. Thus we may view RUV-4 as fitting by GLS with an additional noise-reducing dimensionality reduction step. It is interesting to note just how different this view of RUV-4 is from the one initially presented in Section (3.3).
3.7.5 An Analytic Solution for $\left(\hat{\sigma}_{j}^{2}\right)^{(R U V-i n v)}$

Define

$$
\left(\hat{\sigma}_{j_{\bar{c}}}^{2}\right)^{(\mathrm{RUV}-\mathrm{inv})} \equiv\left(\hat{\sigma}_{j_{\bar{c}}}^{2}\right)^{(\mathrm{m}-1, \mathrm{inv})} .
$$

When it is clear from context, we will drop the superscript and the $\bar{c}$ subscript on the $j$ and refer to this quantity simply as $\hat{\sigma}_{j}^{2}$. The goal of this section is to produce an analytic expression for $\hat{\sigma}_{j}^{2}$.

Combining (114) and (125) we have

$$
\begin{equation*}
\hat{\sigma}_{j}^{2} \equiv \mathbb{E}_{\mathrm{X}}\left[\frac{\left[\left(\mathrm{X}^{\prime}\left(\mathrm{Y}_{c} \mathrm{Y}_{c}^{\prime}\right)^{-1} \mathrm{X}\right)^{-1} \mathrm{X}^{\prime}\left(\mathrm{Y}_{c} \mathrm{Y}_{c}^{\prime}\right)^{-1} \mathrm{Y}_{\star j}\right]^{2}}{1+\hat{b}_{\mathrm{Wx}} \hat{b}_{\mathrm{WX}}^{\prime}}\right] \tag{136}
\end{equation*}
$$

Let D denote the diagonal matrix whose diagonal entries are the first $m-1$ eigenvalues of $R_{X} Y_{c} Y_{c}^{\prime} R_{X}$ and note that $Y_{c} \mathrm{Y}_{c}^{\prime}=\mathrm{D}$. Further note that

$$
\begin{equation*}
\operatorname{Var}\left[\hat{\beta}_{j_{\bar{c}}}^{\star} \mid \mathrm{X}, \mathrm{Y}_{c}\right]=\left(1+\hat{b}_{\mathrm{WX}} \hat{b}_{\mathrm{WX}}^{\prime}\right) \sigma_{j_{\bar{c}}}^{2} \tag{137}
\end{equation*}
$$

and

$$
\begin{equation*}
\operatorname{Var}\left[\hat{\beta}_{j_{\bar{c}}^{\star}}^{\star} \mid \mathrm{X}, \mathrm{Y}_{c}\right]=\left\|\left(\mathrm{X}^{\prime}\left(\mathrm{Y}_{c} \mathrm{Y}_{c}^{\prime}\right)^{-1} \mathrm{X}\right)^{-1} \mathrm{X}^{\prime}\left(\mathrm{Y}_{c} \mathrm{Y}_{c}^{\prime}\right)^{-1}\right\|^{2} \sigma_{j_{\bar{c}}}^{2} \tag{138}
\end{equation*}
$$

and thus

$$
\begin{equation*}
1+\hat{b}_{\mathrm{WX}} \hat{b}_{\mathrm{WX}}^{\prime}=\left\|\left(\mathrm{X}^{\prime}\left(\mathrm{Y}_{c} \mathrm{Y}_{c}^{\prime}\right)^{-1} \mathrm{X}\right)^{-1} \mathrm{X}^{\prime}\left(\mathrm{Y}_{c} \mathrm{Y}_{c}^{\prime}\right)^{-1}\right\|^{2} \tag{139}
\end{equation*}
$$

We may now simplify (136) as

$$
\begin{align*}
\hat{\sigma}_{j}^{2} & =\mathbb{E}_{\mathrm{X}}\left[\frac{\left[\left(\mathrm{X}^{\prime} \mathrm{D}^{-1} \mathrm{X}\right)^{-1} \mathrm{X}^{\prime} \mathrm{D}^{-1} \mathrm{Y}\right]^{2}}{\left\|\left(\mathrm{X}^{\prime} \mathrm{D}^{-1} \mathrm{X}\right)^{-1} \mathrm{X}^{\prime} \mathrm{D}^{-1}\right\|^{2}}\right]  \tag{140}\\
& =\mathbb{E}_{\mathrm{X}}\left[\frac{\mathrm{Y}_{\star j}^{\prime} \mathrm{D}^{-1} \mathrm{X}\left(\mathrm{X}^{\prime} \mathrm{D}^{-1} \mathrm{X}\right)^{-2} \mathrm{X}^{\prime} \mathrm{D}^{-1} \mathrm{Y}_{\star j}}{\left(\mathrm{X}^{\prime} \mathrm{D}^{-1} \mathrm{X}\right)^{-1} \mathrm{X}^{\prime} \mathrm{D}^{-2} \mathrm{X}\left(\mathrm{X}^{\prime} \mathrm{D}^{-1} \mathrm{X}\right)^{-1}}\right]  \tag{141}\\
& =\mathrm{Y}_{\star j}^{\prime} \mathbb{E}_{\mathrm{X}}\left[\frac{\mathrm{D}^{-1} \mathbf{X} \mathrm{X}^{\prime} \mathrm{D}^{-1}}{\mathrm{X}^{\prime} \mathrm{D}^{-2} \mathrm{X}}\right] \mathrm{Y}_{\star j} \tag{142}
\end{align*}
$$

To calculate the expectation, first note that the distribution of $X$ is uniform on the unit ( $m-1$ )-sphere. Let

$$
\begin{align*}
\tilde{\mathrm{X}} & \sim \mathrm{~N}\left(0, I_{\mathrm{m} \times \mathrm{m}}\right)  \tag{143}\\
\rho & \sim \sqrt{\chi_{\mathrm{m}}^{2}} \tag{144}
\end{align*}
$$

and note that if $\rho$ and $X$ are independent then $\tilde{X}$ is equal in distribution $\rho X$. Then

$$
\begin{align*}
E & \equiv \mathbb{E}_{X}\left[\frac{D^{-1} X X^{\prime} D^{-1}}{X^{\prime} D^{-2} X}\right]  \tag{145}\\
& =\mathbb{E}_{\tilde{X}}\left[\frac{D^{-1} \tilde{X} \tilde{X}^{\prime} D^{-1}}{\tilde{X}^{\prime} D^{-2} \tilde{X}}\right] \tag{146}
\end{align*}
$$

For the off-diagonal entries of E we have

$$
\begin{align*}
\mathrm{E}_{i j} & =\mathbb{E}_{\tilde{\mathrm{x}}}\left[\frac{\mathrm{~d}_{i}^{-1} \mathrm{~d}_{j}^{-1} \tilde{\mathrm{X}}_{i} \tilde{\mathrm{X}}_{j}}{\sum_{l=1}^{\mathrm{m}} \mathrm{~d}_{l}^{-2} \tilde{\mathrm{X}}_{l}^{2}}\right]  \tag{147}\\
& =0 \tag{148}
\end{align*}
$$

where $\mathrm{d}_{i} \equiv \mathrm{D}_{i i}$. For the diagonal entries $\mathrm{e}_{i} \equiv \mathrm{E}_{i i}$ of E we have

$$
\begin{equation*}
\mathrm{E}_{i i}=\mathbb{E}_{\tilde{\mathrm{x}}}\left[\frac{\mathrm{~d}_{i}^{-2} \tilde{\mathrm{X}}_{i}^{2}}{\sum_{l=1}^{\mathrm{m}} \mathrm{~d}_{l}^{-2} \tilde{\mathrm{X}}_{l}^{2}}\right] \tag{149}
\end{equation*}
$$

which can be shown to be equal to

$$
\begin{equation*}
\int_{0}^{\infty} \frac{d t}{\mathrm{~d}_{i}^{2}\left(1+2 t / \mathrm{d}_{i}^{2}\right) \prod_{l=1}^{\mathrm{m}} \sqrt{1+2 t / \mathrm{d}_{l}^{2}}} \tag{150}
\end{equation*}
$$

using the results of Magnus (1986). To summarize,

$$
\begin{align*}
\hat{\sigma}_{j}^{2} & =\mathrm{Y}_{\star j}^{\prime} \mathrm{EY}_{\star j}  \tag{151}\\
& =\sum_{i=1}^{\mathrm{m}} \frac{\mathrm{Y}_{i j}^{2}}{\mathrm{~d}_{i}^{2}} \int_{0}^{\infty} \frac{d t}{\left(1+2 t / \mathrm{d}_{i}^{2}\right) \prod_{l=1}^{\mathrm{m}} \sqrt{1+2 t / \mathrm{d}_{l}^{2}}} \tag{152}
\end{align*}
$$

3.7.6 Discussion: $\left(\hat{\sigma}_{j_{\bar{c}}}^{2}\right)^{(R U V-i n v)}$

We wish to develop some intuition for $\hat{\sigma}_{j}^{2}$. Write $\hat{\sigma}_{j}^{2}$ as

$$
\begin{equation*}
\hat{\sigma}_{j}^{2}=\sum_{i=1}^{\mathrm{m}} \mathrm{e}_{i} \mathrm{Y}_{\star j}^{2} \tag{153}
\end{equation*}
$$

It can be shown (see below) that $\sum_{i=1}^{m} \mathrm{e}_{i}=1 . \hat{\sigma}_{j}^{2}$ is therefore a weighted average of $\mathrm{Y}_{\star j}^{2}$. To interpret this result, recall that U is the first $m-1$ left singular vectors of $R_{X} Y_{c}$. If we use the SVD as the method of factor analysis in Step 2 of RUV-4, $\mathbf{U}=\hat{W}_{0}^{(m-1)}$. We therefore assume that

$$
\mathrm{U} \approx\left(W_{0} \mid W_{1}\right)
$$

for an appropriate parameterization of $W_{0}$ and $W_{1}$. Then

$$
\begin{align*}
Y & \approx\left(W_{0} \mid W_{1}\right)^{\prime} Y  \tag{154}\\
& =\binom{W_{0}^{\prime} Y}{W_{1}^{\prime} Y}  \tag{155}\\
& =\binom{\alpha}{0}+\varepsilon . \tag{156}
\end{align*}
$$

A weighted average of $\mathrm{Y}_{\star j}^{2}$ is therefore an appropriate estimator of $\sigma_{j}^{2}$. The weights $\mathrm{e}_{i}$ should be small (ideally 0 ) for $i \leq k$ and large (ideally $\frac{1}{m-k}$ ) for $i>k$.

With the inverse method, this is indeed what happens. The weights $\mathrm{e}_{i}$ are functions of the $\mathrm{d}_{i}$. Now,

$$
\begin{equation*}
\mathrm{d}_{i}=\sum_{j_{c}} \mathrm{Y}_{\mathrm{ij} c}{ }^{2} . \tag{157}
\end{equation*}
$$

For $i>k$ the $\mathrm{d}_{i}$ will all be approximately equal to one another and relatively small. For $i \leq k$ the $\mathrm{d}_{i}$ will be relatively large. We therefore want $e_{i}$ to be small when $d_{i}$ is large and vice versa. Indeed, if we consider a single $\mathrm{d}_{i}$ and hold all other $\mathrm{d}_{i^{\prime}}$ constant, then $\mathrm{e}_{i}$ approaches 1 as $\mathrm{d}_{i}$ approaches 0 . Conversely, $\mathrm{e}_{i}$ is asymptotically proportional to $1 / d_{i}^{2}$ as $d_{i}^{2}$ grows large. See Figure 7.

We now verify the claim $\sum_{i=1}^{m} \mathrm{e}_{i}=1$. Begin by noting

$$
\begin{equation*}
\mathrm{E}=\mathbb{E}_{\mathrm{X}}\left[\mathrm{VV}^{\prime}\right] \tag{158}
\end{equation*}
$$

where

$$
\begin{equation*}
V \equiv \frac{D^{-1} X}{\sqrt{X^{\prime} D^{-2} X}} \tag{159}
\end{equation*}
$$

$$
\mathrm{d}_{i}=1 \quad(i>1)
$$

$\mathrm{d}_{i}=i / 10 \quad(i>1)$

$\mathrm{d}_{i}=10 / i \quad(i>1)$

Figure 7: Plots of $\mathrm{e}_{i}$ as a function of $\mathrm{d}_{i}$. In each plot $\mathrm{m}=100, \mathrm{~d}_{1}$ is varied from $10^{-2}$ to $10^{2}$, and $\mathrm{d}_{i}$ is kept fixed for $i>1$. The solid green line is a plot of $e_{1}$. The solid red line is a plot of $\mathrm{e}_{10}$ (note that in each of the three plots, $d_{10}=1$ ). For purpose of comparison, the green and red dotted lines are plots of $\left(1 / \mathrm{d}_{1}^{2}\right) /\left(\sum_{l=1}^{\mathrm{m}} 1 / \mathrm{d}_{l}^{2}\right)$ and $\left(1 / \mathrm{d}_{10}^{2}\right) /\left(\sum_{l=1}^{\mathrm{m}} 1 / \mathrm{d}_{l}^{2}\right)$.

Note that $\|\mathrm{V}\|=1$. Now,

$$
\begin{align*}
\sum_{i=1}^{\mathrm{m}} \mathrm{e}_{i} & =\operatorname{tr}(\mathrm{E})  \tag{160}\\
& =\operatorname{tr}\left(\mathbb{E}_{\mathrm{X}}\left[\mathrm{~V}^{\prime}\right]\right)  \tag{161}\\
& =\mathbb{E}_{\mathrm{X}}\left[\operatorname{tr}\left(\mathrm{~V}^{\prime}\right)\right]  \tag{162}\\
& =\mathbb{E}_{\mathrm{X}}\left[\operatorname{tr}\left(\mathrm{~V}^{\prime} \mathrm{V}\right)\right]  \tag{163}\\
& =1 \tag{164}
\end{align*}
$$

Next we investigate the distribution of $\hat{\sigma}_{j}^{2}$. It is easy to show that

$$
\begin{equation*}
\mathrm{V}^{\prime} \mathrm{Y}_{\star j}=\frac{\mathrm{X}^{\prime} \mathrm{D}^{-1} \mathrm{X}}{\sqrt{\mathrm{X}^{\prime} \mathrm{D}^{-2} \mathrm{X}}} \mathbb{E}\left[\hat{\beta}_{j}^{\star} \mid \mathrm{X}\right]+\mathrm{V}^{\prime} \varepsilon_{\star j} \tag{165}
\end{equation*}
$$

If we assume

$$
\mathbb{E}\left[\hat{\beta}_{j}^{\star} \mid X\right] \approx 0
$$

it follows that

$$
\begin{equation*}
V^{\prime} Y_{\star j} \approx V^{\prime} \varepsilon_{\star j} \tag{166}
\end{equation*}
$$

and therefore that

$$
\begin{align*}
\hat{\sigma}_{j}^{2} & =\mathbb{E}_{\mathbf{X}}\left[\mathrm{Y}_{\star j}^{\prime} \mathrm{VV}^{\prime} \mathrm{Y}_{\star j}\right]  \tag{167}\\
& \approx \mathbb{E}_{\mathbf{X}}\left[\varepsilon_{\star j}^{\prime} \mathrm{VV}^{\prime} \varepsilon_{\star j}\right]  \tag{168}\\
& =\varepsilon_{\star j}^{\prime} \mathrm{E}_{\star j} . \tag{169}
\end{align*}
$$

Since $\varepsilon_{\star j} \sim N\left(0, \sigma_{j}^{2} I\right)$ we conclude that

$$
\begin{equation*}
\hat{\sigma}_{j}^{2} \dot{\sim} \quad \sigma_{j}^{2} \sum_{i=1}^{\mathrm{m}} \mathrm{e}_{i} \chi_{1, i}^{2} \tag{170}
\end{equation*}
$$

where the $\chi_{1, i}^{2}$ are IID $\chi_{1}^{2}$.
We pause to interpret our analysis. One way to think of the inverse method is as follows: (1) Generate a random $X$. (2) Transform $X$ into $V$. (3) Calculate $s_{j}^{2} \equiv\left(V^{\prime} Y_{\star j}\right)^{2}$. (4) Repeat (1-3) many times and average the resulting $s_{j}^{2}$. The key step is (2). Ideally, $V$ will be a random unit vector in $\mathfrak{R}\left(W_{\perp}\right)$. Then $\left(\mathrm{V}^{\prime} \mathrm{Y}_{\star j}\right)^{2} \sim \sigma_{j}^{2} \chi_{1}^{2}$. However, we cannot sample from $\mathfrak{R}\left(\mathrm{W}_{\perp}\right)$ because W is unknown. We therefore sample from $\mathbb{R}^{m}$ and attempt to orthogonalize to $W$. In step (2) we "effectively orthogonalize" $X$ to $W$ by multiplying X by $\mathrm{D}^{-1} . \mathrm{V}$ is just $\mathrm{D}^{-1} \mathrm{X}$ rescaled to have unit length. V , therefore, is a random unit vector more or less confined to $\mathfrak{R}\left(\mathrm{W}_{\perp}\right)$.

Note that we can imagine generating an infinite number of $s_{j}^{2}$, each of which is approximately distributed as $\sigma_{j}^{2} \chi_{1}^{2}$. However, in (170) we see that the (approximate) distribution of $\hat{\sigma}_{j}^{2}$ can be expressed as the sum of a finite number of rescaled $\chi_{1}^{2}$ random variables. The reason is that the $s_{j}^{2}$ are dependent. They are all calculated using the same observation of $\varepsilon_{\star j}$. The only difference between the $s_{j}^{2}$ is the $V$ that is used. The dependence between the $s_{j}^{2}$ is therefore a consequence of the fact that the V are sampled from a finite dimensional space.

Now suppose we want to calculate the $t$ statistic $t_{j} \equiv \hat{\beta}_{j} / \sqrt{\hat{\sigma}_{j}^{2}}$. If we want to use this $t$ statistic to calculate $p$-values, etc., we must know its distribution. $t_{j}$ does not follow the $t$ distribution because $\hat{\sigma}_{j}^{2}$ does not follow a rescaled $\chi^{2}$ distribution. Therefore, we cannot calculate exact $p$-values using standard methodology and software. However, we might wish to approximate the distribution of $t_{j}$ by some $t$ distribution. In this case it is necessary to approximate the distribution of $\hat{\sigma}_{j}^{2} / \sigma_{j}^{2}$ by some rescaled $\chi^{2}$ distribution. In particular, we must come up with an "effective degrees of freedom." To do so we note that

$$
\begin{align*}
\mathbb{E}\left[\sum_{i=1}^{\mathrm{m}} \mathrm{e}_{i} \chi_{1, i}^{2}\right] & =1  \tag{171}\\
\operatorname{Var}\left[\sum_{i=1}^{\mathrm{m}} \mathrm{e}_{i} \chi_{1, i}^{2}\right] & =2 \sum_{i=1}^{\mathrm{m}} \mathrm{e}_{i}^{2} \tag{172}
\end{align*}
$$

Let

$$
\hat{r} \equiv 1 / \sum_{i=1}^{\mathrm{m}} \mathrm{e}_{i}^{2}
$$

Then

$$
\begin{align*}
\mathbb{E}\left[\frac{\chi_{\hat{r}}^{2}}{\hat{r}}\right] & =1  \tag{173}\\
\operatorname{Var}\left[\frac{\chi_{\hat{r}}^{2}}{\hat{r}}\right] & =2 \sum_{i=1}^{\mathrm{m}} \mathrm{e}_{i}^{2} \tag{174}
\end{align*}
$$

We therefore approximate the distribution of $t_{j}$ by the $t$ distribution with $\hat{r}$ degrees of freedom.
An interesting observation is that $\hat{r}$ may be useful for more than just specifying which $t$ distribution to use when calculating $p$-values. As previously noted, V is a random unit vector more or less confined to $\mathfrak{R}\left(\mathrm{W}_{\perp}\right)$. If it were in fact the case that V was a unit vector distributed uniformly on the unit $\mathrm{m}-k-1$ sphere in $\mathfrak{R}\left(\mathrm{W}_{\perp}\right)$, then $\hat{\sigma}_{j}^{2}$ would have a rescaled $\chi_{\mathrm{m}-k}^{2}$ distribution. Therefore, if in reality $\hat{\sigma}_{j}^{2}$ approximately follows a rescaled $\chi_{\hat{r}}^{2}$ distribution, it may be reasonable to regard $\hat{r}$ as a measure of the "effective dimension" of $\mathrm{W}_{\perp}$. We may therefore choose to estimate $k$ as

$$
\begin{equation*}
\hat{k}^{(\mathrm{inv})} \equiv \mathrm{m}-\hat{r} \tag{175}
\end{equation*}
$$

Although we find this idea quite interesting, we have not found $\hat{k}^{(\text {inv })}$ to perform any better in practice than the $\hat{k}$ described in Section 3.6.6. In some cases it performs notably worse. For example, $\hat{k}^{(\mathrm{inv})}$ may perform poorly when $n_{c}$ is only marginally larger than $m$ and the smaller eigenvalues of $\mathrm{Y}_{c} \mathrm{Y}_{c}^{\prime}$ are noisy.

### 3.7.7 A Brief Note on Preprocessing

In Section 3.7.6 we noted that $\mathrm{e}_{i}$ approaches 1 as $\mathrm{d}_{i}$ approaches 0 . This fact has important implications for data preprocessing. Several common preprocessing steps wholly or partially remove one or more degrees of freedom from the data. Consider a simple example. It is common practice to subtract away gene averages. This is equivalent to setting $Z=1_{m \times 1}$ and multiplying $Y$ by $R_{Z}$. This reduces the rank of $Y$ to $m-1$. The smallest singular value of $Y$ will be 0 and the inverse method will fail. One should not multiply $Y$ by $R_{Z}$ as a preprocessing step. Instead, one should multiply $X$ and $Y$ by $Z_{\perp}^{\prime}$ as suggested in Section 3.6.2.

Subtracting off gene means is just one example of a preprocessing step that wholly or partially removes a degree of freedom from the data. We are in no position to discuss all such examples. Moreover, it is common for a researcher to be given preprocessed data without knowing the exact preprocessing methods that were used. Therefore, we need a general strategy for dealing with preprocessed data. One possible strategy is as follows: First, a researcher makes a scree plot of the (preprocessed) data. The researcher then notes whether there are any abnormally small singular values, and if so, how many. Suppose the researcher observes $n_{s}$ abnormally small singular values. The researcher then takes the final $n_{s}$ left singular vectors of $Y$ and includes these vectors as columns of $Z$. This effectively removes the $n_{s}$ troublesome dimensions of $Y$ by transforming $Y$ into a lower dimensional space.

### 3.8 The Functional Approach

In this section we introduce a new framework for understanding RUV-4 and for developing new, more general methods. In this framework, we transform the problem of estimating $\beta$ into a standard prediction or function estimation problem. Control genes play the role of a training set.

The justification of the approach is rather informal. We find that the "technical assumptions" are less important than the "practical assumptions." In particular, the question of whether $\alpha$ is random or fixed is of secondary importance. By contrast, the assumption that the $\alpha_{\star j_{c}}$ are "representative" of the $\alpha_{\star j_{\bar{c}}}$ takes center stage.

### 3.8.1 Motivating Example

We begin with a motivating example. The example will demonstrate a weakness of RUV-4 and the need for a new approach. Recall that if we model $\alpha_{\star j}$ as random with expectation 0 and variance $\Sigma$, then $\hat{\beta}^{(R U V-i n v)}$ is (approximately) the minimum variance unbiased linear estimator of $\beta$. This is a reasonable estimator to use if $\alpha_{\star j}$ follows a (multivariate) normal distribution. However, if $\alpha$ is not normally distributed, other estimators may be preferable. Our example will illustrate this fact.

Recall the examples of Section 3.4 in which $m=2$ and $k=1$. Recall that $\hat{\beta}=b_{Y X}-\hat{b}_{W X} \hat{\alpha}$, and that we may interpret $\hat{\beta}_{j}$ as the vertical distance from the point $\left(W_{0}^{\prime} Y_{\star j}, X^{\prime} Y_{\star j}\right)$ to the line that passes through the origin and has slope $\hat{b}_{W X}$ (see Figures 1 and 2). In the examples of Section 3.4, $\alpha$ was normally distributed. Here we consider an example in which $\alpha_{j}$ equals either -1 or 1 , each with probability 0.5 . This example is shown in Figure 8. As before, $\hat{\beta}^{(\operatorname{RUV}-4)}$ is given by the vertical distance to the orange line. However, simple visual inspection suffices to convince us that other estimators may be preferable. For example, we have drawn horizontal red lines through the vertical mean of the control genes of each of the two clouds. Instead of using the vertical distance to the orange line, we may prefer to estimate $\beta$ by the vertical distance to the horizontal red lines.

We will now try to formalize the intuition provided by Figure 8. We begin by writing

$$
\begin{equation*}
b_{Y X}=\beta+b_{W X} \alpha+\zeta \tag{176}
\end{equation*}
$$

We may rewrite this as

$$
\begin{equation*}
b_{Y X}=\beta+B(\alpha)+\zeta \tag{177}
\end{equation*}
$$

Figure 8: An example in which $\alpha$ is not normally distributed. See main text for commentary. The simulated data were generated as follows: $X=(0,1)^{\prime} ; W=(1,0.5)^{\prime} ; \alpha_{j}$ equals either -1 or 1 , each with probability $0.5 ; \epsilon_{i j} \sim \mathrm{~N}\left(0, \frac{1}{16}\right) ; \beta_{j} \sim \mathrm{~N}(0,1)$ for $1 \leq j \leq 50 ; \beta_{j}=0$ for $51 \leq j \leq 1000$.
where $B$ denotes the conditional bias of $b_{Y X}$ as a function of $\alpha$, i.e.

$$
\begin{align*}
B(\alpha) & \equiv \mathbb{E}\left[b_{Y X}-\beta \mid \alpha\right]  \tag{178}\\
& =b_{W X} \alpha \tag{179}
\end{align*}
$$

In this context, we may think of $\hat{\beta}^{(\mathrm{RUV}-4)}$ as an "approximately de-biased" version of $b_{Y X}$, i.e.

$$
\begin{align*}
\hat{\beta} & =b_{Y X}-\hat{b}_{W X} \hat{\alpha}  \tag{180}\\
& =b_{Y X}-\hat{B}(\hat{\alpha}) \tag{181}
\end{align*}
$$

where $\hat{B}(\hat{\alpha}) \equiv \hat{b}_{W X} \hat{\alpha}$.
In light of (181), we see that the quality of $\hat{\beta}$ as an estimator of $\beta$ is directly determined by the quality of $\hat{B}(\hat{\alpha})$ as an estimator of $B(\alpha)$. We see intuitively that $\hat{B}(\hat{\alpha})$ is a good estimator of $B(\alpha)$ in Figure 2 but not in Figure 8. What is the difference? Consider the quantity $\mathbb{E}[B(\alpha) \mid \hat{\alpha}]$. We may think of $\mathbb{E}[B(\alpha) \mid \hat{\alpha}]$ as the "best guess" of the unobserved quantity $B(\alpha)$ given the observed quantity $\hat{\alpha}$. Note that $\mathbb{E}[B(\alpha) \mid \hat{\alpha}]$ is a function of $\hat{\alpha}$. Indeed,

$$
\begin{align*}
\mathbb{E}[B(\alpha) \mid \hat{\alpha}] & =\mathbb{E}\left\{\mathbb{E}\left[b_{Y X}-\beta \mid \alpha\right] \mid \hat{\alpha}\right\}  \tag{182}\\
& =\mathbb{E}\left\{\mathbb{E}\left[b_{Y X}-\beta \mid \alpha, \hat{\alpha}\right] \mid \hat{\alpha}\right\}  \tag{183}\\
& =\mathbb{E}\left[b_{Y X}-\beta \mid \hat{\alpha}\right]  \tag{184}\\
& =\mathbb{B}(\hat{\alpha}) \tag{185}
\end{align*}
$$

where

$$
\begin{equation*}
\mathbb{B}(\hat{\alpha}) \equiv \mathbb{E}\left[b_{Y X}-\beta \mid \hat{\alpha}\right] . \tag{186}
\end{equation*}
$$

We may think of $\mathbb{B}(\hat{\alpha})$ as the "ideal" estimator of $B(\alpha)$. We cannot calculate $\mathbb{B}(\hat{\alpha})$ itself because we do not know the function $B$, the distribution of $\alpha$, or $\sigma^{2}$. However, it is nonetheless the case that a good estimator of $B(\alpha)$ will be some function of $\hat{\alpha}$ that closely approximates $\mathbb{B}(\hat{\alpha})$.

It turns out that $\hat{B}_{j}(\hat{\alpha})$ closely approximates $\mathbb{B}_{j}(\hat{\alpha})$ if $\alpha_{j}$ is normally distributed with expectation 0 . To see this, assume

$$
\begin{equation*}
\alpha_{j} \sim N\left(0, \psi^{2}\right) \tag{187}
\end{equation*}
$$

It follows that

$$
\begin{align*}
\mathbb{B}_{j}(\hat{\alpha}) & =\mathbb{E}\left[B_{j}(\alpha) \mid \hat{\alpha}\right]  \tag{188}\\
& =\mathbb{E}\left[b_{W X} \alpha_{j} \mid \hat{\alpha}_{j}\right]  \tag{189}\\
& =b_{W X} \mathbb{E}\left[\alpha_{j} \mid \hat{\alpha}_{j}\right]  \tag{190}\\
& =b_{W X}\left(\frac{\psi^{2}}{\psi^{2}+\sigma_{j}^{2}}\right) \hat{\alpha}_{j}  \tag{191}\\
& =\mathbb{E}\left[\hat{b}_{W X}\right] \hat{\alpha}_{j}  \tag{192}\\
& \approx \hat{b}_{W X} \hat{\alpha}_{j}  \tag{193}\\
& =\hat{B}_{j}(\hat{\alpha}) . \tag{194}
\end{align*}
$$

Thus, $\hat{B}_{j}(\hat{\alpha}) \approx \mathbb{B}_{j}(\hat{\alpha})$ and we consider $\hat{B}_{j}(\hat{\alpha})$ to be a good estimator of $B_{j}(\alpha)$.
In the example of Figure 8 , however, $\alpha$ is not normally distributed and $\mathbb{B}_{j}(\hat{\alpha})$ is no longer a linear function of $\hat{\alpha}_{j}$. Indeed, it can be shown that in this particular example

$$
\begin{equation*}
\mathbb{B}_{j}(\hat{\alpha})=\frac{1}{2}\left(\frac{e^{8\left(\hat{\alpha}_{j}+1\right)^{2}}-e^{8\left(\hat{\alpha}_{j}-1\right)^{2}}}{e^{8\left(\hat{\alpha}_{j}+1\right)^{2}}+e^{8\left(\hat{\alpha}_{j}-1\right)^{2}}}\right) \tag{195}
\end{equation*}
$$

This function is plotted in Figure 8 in blue. It is no longer true that $\hat{B}_{j}(\hat{\alpha}) \approx \mathbb{B}_{j}(\hat{\alpha})$; the orange line does not approximate the blue curve. $\hat{B}(\hat{\alpha})$ is no longer a good estimator of $B(\alpha)$.

### 3.8.2 The Functional Approach, Part I

To summarize our discussion so far: $b_{Y X}=\beta+b_{W X} \alpha+\zeta$. In RUV-4, we estimate $B(\alpha)=b_{W X} \alpha$ by $\hat{B}(\hat{\alpha})=\hat{b}_{W X} \hat{\alpha}$ and set $\hat{\beta}=b_{Y X}-\hat{B}(\hat{\alpha})$. This works well if $\alpha$ is normally distributed, but does not necessarily work well otherwise. The important point to notice is that when we estimate $B(\alpha)$ in RUV-4 we effectively do so in two parts: we estimate the linear function $B$ by the linear function $\hat{B}$, and we estimate $\alpha$ by $\hat{\alpha}$. We then combine these and use $\hat{B}(\hat{\alpha})$ as our estimate of $B(\alpha)$. This seams reasonable at first, but as we have seen, the "best" estimate of $B(\alpha)$ is not necessarily linear in $\hat{\alpha}$.

These considerations inspire a new approach. We do not attempt to estimate $W$ and then estimate $\beta$ by linear regression. We do not focus our attention on the estimation of $b_{W X}$. We do not estimate $B(\alpha)$ by $\hat{B}(\hat{\alpha})$. Rather, our goal is to directly estimate the function $\mathbb{B}$. Equipped with an estimate $\hat{\mathbb{B}}$ of $\mathbb{B}$ we then estimate $\beta$ by $b_{Y X}-\hat{\mathbb{B}}(\hat{\alpha})$. We call this the functional approach, or RUV-fun. Note that unlike RUV-2 or RUV-4, RUV-fun does not refer to a specific algorithm but rather to a general strategy; we may estimate $\mathbb{B}$ by any method we see fit. Indeed, we may view RUV-4 as a special case of RUV-fun.

How might we estimate $\mathbb{B}$ ? As always, the key is the control genes. Recall that

$$
\begin{align*}
b_{Y X} & =\beta+B(\alpha)+\zeta  \tag{196}\\
& \approx \beta+\mathbb{B}(\hat{\alpha})+\zeta \tag{197}
\end{align*}
$$

and thus for the control genes we have

$$
\begin{equation*}
\left(b_{Y X}\right)_{c} \approx \mathbb{B}_{c}(\hat{\alpha})+\zeta_{c} \tag{198}
\end{equation*}
$$

We can use $\left(b_{Y X}\right)_{c}$ and $\hat{\alpha}_{c}$ to help us estimate $\mathbb{B}$. However, we also need an additional assumption. We need an additional assumption because $\mathbb{B}$ is a vector of $n$ functions:

$$
\begin{equation*}
\mathbb{B}(\hat{\alpha})=\left(\mathbb{B}_{1}\left(\hat{\alpha}_{\star 1}\right), \mathbb{B}_{2}\left(\hat{\alpha}_{\star 2}\right), \ldots, \mathbb{B}_{n}\left(\hat{\alpha}_{\star n}\right)\right) \tag{199}
\end{equation*}
$$

In principle, each of these $\mathbb{B}_{j}$ may be different functions. However, we only have one observation of each $\hat{\alpha}_{\star j}$ and each $\left(b_{Y X}\right)_{j}$. It is not feasible to estimate the entire function $\mathbb{B}_{j}$ from a single observation. Moreover, the fundamental idea of the functional approach is to use the biases of the control genes to help us estimate the biases of the non-control genes. This is not possible if we treat each $\mathbb{B}_{j}$ as its own distinct entity. We need an assumption that will relate the $\mathbb{B}_{j}$ to one another in some way, and allow us to estimate the $\mathbb{B}_{j}$ jointly. We are in no position to estimate all $n \mathbb{B}_{j}$ separately.

Faced with this dilemma, we make a very strong technical assumption. We assume that the $\left(\hat{\alpha}_{\star j}, B_{j}(\alpha)\right)$ pairs are IID. This is the key technical assumption of the functional approach. From this assumption it follows that

$$
\mathbb{B}_{1}=\mathbb{B}_{2}=\ldots=\mathbb{B}_{n}
$$

We can now define

$$
\mathbb{B}_{0} \equiv \mathbb{B}_{j}
$$

$\mathbb{B}_{0}$ is the function that we will estimate.
Each $\left(\hat{\alpha}_{\star j_{c}},\left(b_{Y X}\right)_{j_{c}}\right)$ pair provides an estimate of $\mathbb{B}_{0}$ evaluated at a specific point. In other words, control genes play the role of a training set in a prediction problem. The $\hat{\alpha}_{\star j_{c}}$ are the predictors, and the $\left(b_{Y X}\right)_{j_{c}}$ are the response variables. We may choose to estimate $\mathbb{B}_{0}$ by any of a number of methods. We need not restrict ourselves to linear functions, or even parametric functions. We have at our disposal the numerous methods available in the prediction, function estimation, and machine learning literature.

### 3.8.3 The Assumptions of RUV-fun

In this section we discuss the assumptions of the functional approach. We distinguish between "technical assumptions" and "practical assumptions." The technical assumptions include the modeling assumptions of Section 3.1 and the assumption that the $\left(\hat{\alpha}_{\star j}, B_{j}(\alpha)\right)$ pairs are IID. We find the technical assumptions implausible. We also argue that violations of the technical assumptions do not necessarily lead the functional approach to perform poorly. The practical assumptions are less rigorous than the technical assumptions. We find these assumptions plausible. We also believe these assumptions must be satisfied to ensure the functional approach performs well. We argue that that the practical assumptions may also be used as an informal justification of the functional approach.

We begin with a more careful look at the main technical assumption of RUV-fun. The main technical assumption of RUV-fun is that the pairs $\left(\hat{\alpha}_{\star j}, B_{j}(\alpha)\right)$ are IID. This assumption does not follow as a necessary consequence of the modeling assumptions presented in Section 3.1. For example, suppose we model $\alpha$ as fixed. Then the $\hat{\alpha}_{\star j}$ will not be IID. Suppose instead we model the $\alpha_{\star j}$ as random and IID. Even then, the $\hat{\alpha}_{\star j}$ need not be IID. Recall that $\hat{\alpha}_{\star j}=\alpha_{\star j}+\xi_{\star j}$. The $\xi_{\star j}$ are not IID unless $\sigma_{j}^{2}=\sigma_{0}^{2}$ for all $j$. However, if we do assume that the $\alpha_{\star j}$ are IID and that $\sigma_{j}^{2}=\sigma_{0}^{2}$ for all $j$, it does follow that the pairs $\left(\hat{\alpha}_{\star j}, B_{j}(\alpha)\right)$ are IID.

To satisfy the main technical assumption of the functional approach we assume that the $\alpha_{\star j}$ are IID and $\sigma_{j}^{2}=\sigma_{0}^{2}$ for all $j$. We find the assumption that $\sigma_{j}^{2}=\sigma_{0}^{2}$ for all $j$ to be implausible. However, we also believe this assumption to be relatively unimportant. Recall the discussion of Section 3.7.4. We noted that $\frac{1}{n_{c}}\left(Y_{c} Y_{c}^{\prime}\right)$ is a biased estimate of $\Sigma_{j}$ unless $\sigma_{j}^{2}=\bar{\sigma}_{c}^{2}$. Under the assumption that $\sigma_{j}^{2}=\sigma_{0}^{2}$ for all $j, \sigma_{j}^{2}=\bar{\sigma}_{c}^{2}=\sigma_{0}^{2}$ and $\frac{1}{n_{c}}\left(Y_{c} Y_{c}^{\prime}\right)$ is an unbiased estimate of $\Sigma_{j}$. We may view the consequences of a violation of the assumption that $\sigma_{j}^{2}=\sigma_{0}^{2}$ as analogous to the consequences of using a biased estimate of $\Sigma_{j}$ in Section 3.7.4. We argue
in Section A. 3 of the SM that the consequences of using a biased estimate of $\Sigma_{j}$ are not severe. Likewise, we do not believe that the consequences of a violation of the assumption that $\sigma_{j}^{2}=\sigma_{0}^{2}$ are very severe.

We have just argued that the main technical assumption of the functional approach is false but that in practice this doesn't matter. This is somewhat comforting. However, the falsity of the technical assumptions does raise an unsettling conceptual problem. It is no longer clear what we are estimating! If the $\left(\hat{\alpha}_{\star j}, B_{j}(\alpha)\right)$ pairs are not $\operatorname{IID}$, it is false that $\mathbb{B}_{1}=\mathbb{B}_{2}=\ldots=\mathbb{B}_{n}$. If it is false that $\mathbb{B}_{1}=\mathbb{B}_{2}=\ldots=\mathbb{B}_{n}$, it follows that $\mathbb{B}_{0}$, as we have defined it, does not exist. This is disturbing, since the goal of the functional approach is to estimate $\mathbb{B}_{0}$.

Is there a better way to define $\mathbb{B}_{0}$ ? Ideally, $\mathbb{B}_{0}$ would satisfy three criteria. Firstly, we would like that $\mathbb{B}_{0}\left(\alpha_{\star j}\right)$ approximately equal $\mathbb{B}_{j}\left(\alpha_{\star j}\right)$ with high probability. Secondly, we want $\mathbb{B}_{0}$ to exist even when $\mathbb{B}_{j} \neq \mathbb{B}_{j^{\prime}}$. Finally, we would like $\mathbb{B}_{0}$ to have some relatively simple, real-world interpretation. Unfortunately, we are unable to provide any such definition of $\mathbb{B}_{0}$. For example, suppose we try defining $\mathbb{B}_{0}$ as the average of the $\mathbb{B}_{j}$. This definition of $\mathbb{B}_{0}$ would satisfy the second criterion, but not the first. To see this, suppose that $\alpha$ is fixed. In this case, each $\mathbb{B}_{j}$ is simply a constant function. Specifically, $\mathbb{B}_{j}(\hat{\alpha})=W \alpha_{\star j}$. Thus, the average of the $\mathbb{B}_{j}$ is also just a constant function. Alternatively, suppose we try defining $\mathbb{B}_{0}$ as $\mathbb{E}\left[B_{J}(\alpha) \mid \hat{\alpha}_{\star J}\right]$ where $J$ is a random variable distributed uniformly on $\{1,2, \ldots, n\}$. This may satisfy the first two criteria, but it is not clear to us what the real-world interpretation of this function might be.

Fortunately, from a purely practical point of view, it does not necessarily matter if $\sigma_{j}^{2}=\sigma_{0}^{2}$, or if the $\alpha_{\star j}$ are IID, or even if $\mathbb{B}_{0}$ exists. What matters is whether the $\left(\hat{\alpha}_{\star j}, B_{j}(\alpha)\right)$ are well described by the function $\hat{\mathbb{B}}_{0}$ that we have fit to the $\left(\hat{\alpha}_{\star j_{c}},\left(b_{Y X}\right)_{j_{c}}\right)$. This is still possible even if the technical assumptions are violated.

When can we expect the $\left(\hat{\alpha}_{\star j}, B_{j}(\alpha)\right)$ to be well described by $\hat{\mathbb{B}}_{0}$ ? There is no simple answer. However, for guidance, we now present two important "practical assumptions" of the functional approach. The practical assumptions are relatively informal, and we do not attempt to treat them rigorously. Nonetheless, these assumptions warrant serious consideration, and are critical to the success of the functional approach. The first assumption is that genes with similar $\hat{\alpha}_{\star j}$ experience similar biases. In other words,

$$
\begin{equation*}
\hat{\alpha}_{\star j} \approx \hat{\alpha}_{\star j^{\prime}} \quad \rightarrow \quad B_{j}(\alpha) \approx B_{j^{\prime}}(\alpha) \tag{200}
\end{equation*}
$$

The second is that the control genes are representative of the other genes. In particular, the (realized) distribution of the $\hat{\alpha}_{\star j_{c}}$ must be roughly the same as the distribution of the $\hat{\alpha}_{\star j_{\bar{c}}}$. Moreover, the biases of the control genes must not differ systematically from those of the non-control genes.

These are strong assumptions, and have important implications for selecting an appropriate set of control genes. As a concrete example, consider spike-in controls (see Gagnon-Bartsch and Speed (2012) for a discussion of spike-in controls). These controls likely exhibit unwanted variation related to their own preparation. Other genes do not. The biases of the spike-in controls are therefore likely to differ systematically from the biases of non-control genes. Spike-in controls may be a poor choice for the functional approach.

The importance of the "practical assumptions" is not limited to the selection of control genes. These two assumptions may also be used as an informal - but relatively realistic - justification of the functional approach. If we assume (200) and that the control genes are representative, it follows that we may very roughly approximate the bias of gene $j$ by the $\left(b_{Y X}\right)_{j_{c}}$ of the nearest control gene. In other words, we may very roughly approximate $B_{j}(\alpha)$ by $\left(b_{Y X}\right)_{c(j)}$ where

$$
c(j)=\underset{j_{c}}{\operatorname{argmin}} d\left(\hat{\alpha}_{\star j}, \hat{\alpha}_{\star j_{c}}\right)
$$

and where $d$ is some appropriate distance measure. Of course, we may get a better estimate of $B_{j}(\alpha)$ by taking the average of the $\left(b_{Y X}\right)_{j_{c}}$ of several nearby control genes instead of just the single closest, and may get a still better estimate by fitting some curve to the $\left(b_{Y X}\right)_{j_{c}}$ of all the control genes. In this way, we are led back to the functional approach. Although informal, we might consider this to be the most appropriate justification for the functional approach. For better or worse, the approach is intrinsically ad hoc.

To conclude this section, we consider the utility of the technical assumptions. We have argued at several points that the technical assumptions are neither plausible nor necessary for the success of the functional approach. However, we do not wish to imply that the technical assumptions are useless. Consideration of the
technical assumptions can be very helpful in alerting us to potential problems. If the technical assumptions were true, they would justify the use of the functional approach. Thus, by considering the ways in which the assumptions are false, we are led to consider ways in which the functional approach might fail. An example is our discussion regarding the violation of the assumption that $\sigma_{j}^{2}=\sigma_{0}^{2}$. We ultimately concluded that the consequences of a violation of this assumption were not severe. However, we arrived at this conclusion only after investigating the matter in A. 3 of the SM. Finally, note that most off-the-shelf prediction algorithms effectively assume the $\left(\hat{\alpha}_{\star j}, B_{j}(\alpha)\right)$ to be IID. Some algorithms may be more sensitive to violations of this assumption than others.

### 3.8.4 RUV-4 as RUV-fun

We noted in Section 3.8.2 that RUV-4 may be interpreted as a special case of RUV-fun. More specifically, we may interpret RUV-4 as a parametric version of RUV-fun in which we constrain $\hat{\mathbb{B}}_{0}$ to be a linear function that passes through the origin, and in which we fit $\hat{\mathbb{B}}_{0}$ by least squares. In this section we explore more fully the interpretation of RUV-4 as a special case of RUV-fun.

We consider first the rationale for constraining $\hat{\mathbb{B}}_{0}$ to be a linear function that passes through the origin. In the derivation of RUV-4 in Section 3.3 we do not address this issue explicitly. Implicitly, however, we rationalize constraining $\hat{\mathbb{B}}_{0}$ to be a linear function that passes through the origin on the grounds that $B$ is a linear function that passes through the origin. As the example of Section 3.8.1 shows, however, linearity of $B$ does not imply linearity of $\hat{\mathbb{B}}_{0}$. If we assume that $\alpha_{\star j} \sim N(0, \Sigma)$ for all $j$, it follows that $\mathbb{B}_{0}$ is a linear function that passes through the origin. This would justify the constraint on $\hat{\mathbb{B}}_{0}$. However, as noted in Section 3.5.4, we find this assumption implausible.

In the RUV-fun framework, the rationale for constraining $\hat{\mathbb{B}}_{0}$ to be a linear function that passes through the origin is primarily empirical. It is of secondary importance whether the $\alpha_{\star j}$ are actually distributed as $N(0, \Sigma)$, or whether $\alpha$ is even random. Of primary importance is whether the $\left(\hat{\alpha}_{\star j}, B_{j}(\alpha)\right)$ pairs are well described by $\hat{\mathbb{B}}_{0}$. The best justification for constraining $\hat{\mathbb{B}}_{0}$ to be a linear function that passes through the origin is that, in practice, it does seem that the $\left(\hat{\alpha}_{\star j}, B_{j}(\alpha)\right)$ pairs are well described by such a function. See Section 5 for evidence.

We now revisit the discussion of Section 3.4. In Section 3.4 we observed that RUV-2 seems to provide a better estimate of $W$ than RUV-4, but RUV-4 nonetheless provides a better estimate of $\beta$. By viewing RUV4 as a special case of RUV-fun we may gain perspective on this curious fact. In the RUV-fun framework, what matters is that the $\left(\hat{\alpha}_{\star j}, B_{j}(\alpha)\right)$ are well described by a linear function $\hat{\mathbb{B}}_{0}$ that passes through the origin. Unlike with RUV-4, with RUV-fun we do not care whether the coefficients of the linear function $\hat{\mathbb{B}}_{0}$ provide a good approximation of $b_{W X}$. If we view RUV-4 simply as RUV-fun in disguise, we really don't care about $\hat{W}$ at all. $\hat{W}$ is at best a means to an ends, at worst a distraction. Said another way, $\hat{W}$ does not determine $\hat{\beta} ; \hat{\beta}$ determines $\hat{W}$.

An example of this "abuse of $\hat{W}$ " can be seen in (190) - (192). In (191) we write $\mathbb{B}_{j}(\hat{\alpha})$ as the product of three terms: $b_{W X}$, a shrinkage factor $\psi^{2} /\left(\psi^{2}+\sigma_{j}^{2}\right)$, and $\hat{\alpha}_{j}$. Conceptually, the shrinkage factor is best understood as something having to do with $\alpha_{j}$ and $\hat{\alpha}_{j}$. In particular,

$$
\begin{equation*}
\mathbb{E}\left[\alpha_{j} \mid \hat{\alpha}_{j}\right]=\left(\frac{\psi^{2}}{\psi^{2}+\sigma_{j}^{2}}\right) \hat{\alpha}_{j} \tag{201}
\end{equation*}
$$

However, in RUV-4, we effectively incorporate the shrinkage factor into our estimate of $b_{W X}$. Recall that

$$
\begin{equation*}
\mathbb{E}\left[\hat{b}_{W X}\right]=b_{W X}\left(\frac{\psi^{2}}{\psi^{2}+\sigma_{j}^{2}}\right) \tag{202}
\end{equation*}
$$

If we wanted to more faithfully follow the general strategy of RUV-4 as it was presented in Section 3.3, we would first want to find an unbiased, or nearly unbiased, estimate of $b_{W X}$. We could then construct a more proper estimate of $W$. Finally, instead of estimating $\alpha_{j}$ by $\hat{\alpha}_{j}$, we would instead estimate $\alpha$ by some estimate of $\mathbb{E}\left[\alpha_{j} \mid \hat{\alpha}_{j}\right]$, e.g. $\left[\hat{\psi}^{2} /\left(\hat{\psi}^{2}+\hat{\sigma}_{j}^{2}\right)\right] \hat{\alpha}_{j}$, where $\hat{\psi}^{2}$ is some estimate of $\psi^{2}$.

### 3.8.5 The Functional Approach, Part II

Until now we have retained the modeling assumptions of Section 3.1. In Section 3.8.1 we considered an "unusual" distribution of $\alpha$, but we did not depart from the model of Section 3.1. In Section 3.8.2 we introduced the assumption that the $\left(\hat{\alpha}_{\star j}, B_{j}(\alpha)\right)$ pairs are IID. This assumption added to, but did not modify or replace, the assumptions of Section 3.1.

We have retained the modeling assumptions of Section 3.1 until now so that we could discuss the functional approach in a familiar setting. In Section 3.8.1 we demonstrated that the functional approach could be used to develop better methods to estimate $\beta$. In Section 3.8 .3 we discussed the nature of the assumptions of the functional approach. In Section 3.8.4 we demonstrated that the functional approach could be used to better understand RUV-4. All of this was possible in the familiar setting of the model of Section 3.1.

However, the functional approach is most powerful when we abandon the model of Section 3.1. We now present a new model. Define $m, n, X$, and $Y$ as we have previously. Let $\mathcal{P}$ be a $K \times n$ matrix of observed predictors. Let $\mathcal{S} \equiv X^{\prime} Y=b_{Y X}$ denote the observed "signal of interest." Let $\beta$ be an unobserved $1 \times n$ parameter of interest. Let $f$ denote some unknown function. We model $\mathcal{S}_{j}$ as

$$
\begin{equation*}
\mathcal{S}_{j}=\beta_{j}+f\left(\mathcal{P}_{\star j}\right)+\delta_{j} . \tag{203}
\end{equation*}
$$

We assume that $\mathcal{P} \Perp \delta$ and that the $\left(\mathcal{P}_{\star j}, \delta_{j}\right)$ are IID. We do not assume here any constraints on the function $f$, nor do we assume here anything about the distribution of $\delta$. However, in any given application of the functional approach, we will need to make assumptions regarding the form of $f$ and the distribution of $\delta$. Note that the interpretation of $\beta$ here is similar, though not identical, to its interpretation in Section 3.1. By abuse of notation, we use the same symbol. Likewise, the interpretation of $K$ here is similar, but not identical, to its former interpretation. Note that $\delta$ here is not related in any way to the $\delta$ of Section 3.7.4. We assume that $\beta_{c}=0$. To estimate $f$ we note that $\mathcal{S}_{j_{c}}=f\left(\mathcal{P}_{\star j_{c}}\right)+\delta_{j_{c}}$ and fit $\hat{f}$ using any method of our choosing. We estimate $\beta$ as the difference between the observed signal and the predicted signal:

$$
\begin{equation*}
\hat{\beta}_{j}^{(\mathrm{RUV}-\mathrm{fun})} \equiv \mathcal{S}_{j}-\hat{f}\left(\mathcal{P}_{\star j}\right) \tag{204}
\end{equation*}
$$

The most important feature of our new model is that we place no restrictions on what we may include in $\mathcal{P}$. To be sure, we will often wish to fill $m-1$ rows of $\mathcal{P}$ with $X_{\perp}^{\prime} Y$. (Note that by setting $\mathcal{P}=X_{\perp}^{\prime} Y$, constraining $\hat{f}$ to be a linear function that passes through the origin, and fitting $\hat{f}$ by least squares, we recover $\left.\hat{\beta}^{(\mathrm{RUV}-\mathrm{inv})}\right)$. However, we may also include any other variables of our choosing. We may include non-linear features of the data. For example, we may include an initial estimate of $\sigma^{2}$. We may also include "outside" sources of information. For example, we may wish to include the GC content of the genes. Including information on GC content may be particularly useful when applying RUV-fun to RNA-seq data.

### 3.9 Variations and Extensions

In this section we consider four unrelated enhancements to the basic RUV methods. The first, the ridged inverse method, is useful when $n_{c}$ is small. The second, RUV-1, is primarily of theoretical interest. The third, empirical controls, is useful when no control genes are available but $\beta$ is known to be sparse. The fourth, rescaled and empirical variances, improves control of the type 1 error rate.

### 3.9.1 The Ridged Inverse Method (RUV-rinv)

In Section 3.6 .4 we noted that setting $K$ too large may substantially increase the variance of $\hat{\beta}$ if $n_{c}$ is not large. This is a problem, since $\hat{\beta}^{(\mathrm{RUV}-\mathrm{inv})}=\hat{\beta}^{(\mathrm{RUV}-4)}$ with $K=m-1$. If $n_{c}$ is only slightly larger than $m$, $\hat{\beta}^{(R U V-i n v)}$ will not be a good estimator of $\beta$. This is particularly easy to see in the context of the functional approach. Let $\mathcal{P}=X_{\perp}^{\prime} Y$, constrain $\hat{f}$ to be a linear function that passes through the origin, and fit $\hat{f}$ by least squares; i.e. let $\overline{\hat{f}}(u)=\mathcal{S}_{c} \mathcal{P}_{c}^{\prime}\left(\mathcal{P}_{c} \mathcal{P}_{c}^{\prime}\right)^{-1} u$. The resulting estimate of $\beta$ is $\mathcal{S}-\mathcal{S}_{c} \mathcal{P}_{c}^{\prime}\left(\mathcal{P}_{c} \mathcal{P}_{c}^{\prime}\right)^{-1} \mathcal{P}$ and is identical to $\hat{\beta}^{(\text {RUV -inv })}$. (It may be helpful to note that $\mathcal{S}-\mathcal{S}_{c} \mathcal{P}_{c}^{\prime}\left(\mathcal{P}_{c} \mathcal{P}_{c}^{\prime}\right)^{-1} \mathcal{P}$ is a combination of (29) and (37), expressed in the formalism of the functional approach.) Now, the quality of $\hat{\beta}^{(\mathrm{RUV}-\mathrm{inv})}$ as an estimator
of $\beta$ depends on the quality of $\hat{f}$ as an estimator of $f$. If $n_{c}$ is only slightly larger than $m, \hat{f}$ will be noisy, and $\hat{\beta}^{(\mathrm{RUV}-\mathrm{inv})}$ will be too.

One possible solution is to use ridge regression. (Readers unfamiliar with ridge regression may wish to consult, e.g. Friedman et al. (2009).) The ridge regression estimate of $f(u)$ is

$$
\begin{equation*}
\hat{f}(u)=\mathcal{S}_{c} \mathcal{P}_{c}^{\prime}\left(\mathcal{P}_{c} \mathcal{P}_{c}^{\prime}+\lambda I\right)^{-1} u \tag{205}
\end{equation*}
$$

where $\lambda \geq 0$ is a tuning parameter. The hope is that, for a suitable choice of $\lambda$, the ridge regression estimate of $f$ will be substantially less noisy than the non-ridged estimate, and only a little bit more biased.

We define the "ridged inverse" estimator of $\beta$ as

$$
\begin{equation*}
\hat{\beta}^{(\text {RUV }- \text { rinv })}(\lambda)=\mathcal{S}-\mathcal{S}_{c} \mathcal{P}_{c}^{\prime}\left(\mathcal{P}_{c} \mathcal{P}_{c}^{\prime}+\lambda I\right)^{-1} \mathcal{P} \tag{206}
\end{equation*}
$$

We drop the superscript when it is clear from context. We also drop the explicit dependence on $\lambda$.
Let us now provide an expression for $\hat{\beta}^{(\text {RUV }}$-rinv) in terms of more familiar quantities. Note that in the notation of Section 3.7,

$$
\begin{equation*}
\hat{\beta}=X^{\prime} Y-X^{\prime} Y_{c} Y_{c}^{\prime} X_{\perp}\left(X_{\perp}^{\prime} Y_{c} Y_{c}^{\prime} X_{\perp}+\lambda I\right)^{-1} X_{\perp}^{\prime} Y \tag{207}
\end{equation*}
$$

Note also that $X^{\prime}(\lambda I) X_{\perp}=0$ because $X^{\prime} X_{\perp}=0$, and that $X_{\perp}^{\prime}(\lambda I) X_{\perp}=\lambda I$ because $X_{\perp}^{\prime} X_{\perp}=I$. Thus

$$
\begin{equation*}
\hat{\beta}=X^{\prime} Y-X^{\prime}\left(Y_{c} Y_{c}^{\prime}+\lambda I\right) X_{\perp}\left[X_{\perp}^{\prime}\left(Y_{c} Y_{c}^{\prime}+\lambda I\right) X_{\perp}\right]^{-1} X_{\perp}^{\prime} Y \tag{208}
\end{equation*}
$$

Using an argument analogous to that in (118)-(125), we conclude

$$
\begin{equation*}
\hat{\beta}=\left[X^{\prime}\left(Y_{c} Y_{c}^{\prime}+\lambda I\right)^{-1} X\right]^{-1} X^{\prime}\left(Y_{c} Y_{c}^{\prime}+\lambda I\right)^{-1} Y \tag{209}
\end{equation*}
$$

This is an appealing result. As with $\hat{\beta}^{(\text {RUV -inv })}$, we see that $\hat{\beta}^{\text {(RUV-rinv) }}$ can be interpreted as a GLS-like estimator. The only difference is that we have ridged our (presumably noisy) estimate of $\Sigma_{j}$, and now set $\hat{\Sigma}_{j}=Y_{c} Y_{c}^{\prime}+\lambda I$ instead of $\hat{\Sigma}_{j}=Y_{c} Y_{c}^{\prime}$.

A few practical matters remain: how do we estimate $\sigma^{2}$, and how do we choose a value for $\lambda$ ? The first is easy. To estimate $\sigma^{2}$ we simply use the inverse method. The results of Section 3.7 .5 carry over, with $\mathrm{Y}_{c} \mathrm{Y}_{c}^{\prime}$ replaced by $\mathrm{Y}_{c} \mathrm{Y}_{c}^{\prime}+\lambda I$.

We now consider $\lambda$. We do not feel there is any one "best" way to choose $\lambda$. We present here one method we have found to work reasonably well in practice. We begin with the observation that, under the assumptions of Section 3.7.4,

$$
\begin{equation*}
\mathbb{E}\left[Y_{c} Y_{c}^{\prime}\right]=n_{c}\left(\Sigma+\bar{\sigma}_{c}^{2} I\right) \tag{210}
\end{equation*}
$$

Thus, given our assumption that $\Sigma$ is rank $k<m$, the smallest eigenvalue of $\mathbb{E}\left[Y_{c} Y_{c}^{\prime}\right]$ is $n_{c} \bar{\sigma}_{c}^{2}$. However, the smallest eigenvalue of $Y_{c} Y_{c}^{\prime}$ may be considerably smaller. Indeed, the smallest eigenvalue of $Y_{c} Y_{c}^{\prime}$ may even be 0 if we consider the case $n_{c}<m$. We might therefore wish to set $\lambda$ equal to

$$
\begin{align*}
\lambda_{0} & =n_{c} \bar{\sigma}_{c}^{2}  \tag{211}\\
& =\sum_{j_{c}} \sigma_{j_{c}}^{2} . \tag{212}
\end{align*}
$$

This would ensure that every eigenvalue of $Y_{c} Y_{c}^{\prime}+\lambda I$ is at least as big as the smallest eigenvalue of $\mathbb{E}\left[Y_{c} Y_{c}^{\prime}\right]$, and thus that none of our eigenvalues are "too small."

Of course, $\sigma^{2}$ is unknown and so is $\lambda_{0}$. However, we can estimate $\lambda_{0}$ if we have an estimate of $\sigma^{2}$. This raises a tricky problem: we can estimate $\sigma^{2}$ once we have a value for $\lambda$, but our desired value of $\lambda$ requires an estimate of $\sigma^{2}$. Our solution to this problem is to estimate $\sigma^{2}$ using some other version of RUV. Which version of RUV is best for this purpose? RUV-inv is a poor choice. As mentioned in Section 3.6.6, when
$n_{c}$ is only slightly larger than $m, \hat{b}_{W X}$ is overfitted to the control genes, and the variance of $\hat{\beta}_{j_{c}}$ is less than $\sigma_{j_{c}}^{2}\left(1+\hat{b}_{W X} \hat{b}_{W X}^{\prime}\right)$. As a result, the RUV-inv estimate of $\sigma_{c}^{2}$ tends to be too small. Instead, we use the RUV-4 estimate, with $K=\hat{k}$. This estimate tends to be of the right size. We define

$$
\begin{equation*}
\hat{\lambda}_{0}=\sum_{j_{c}}\left(\hat{\sigma}_{j_{c}}^{2}\right)^{(\hat{k})} . \tag{213}
\end{equation*}
$$

This is the value of $\lambda$ we use in all of the applications of RUV-rinv in this paper.
Again, note that $\hat{\lambda}_{0}$ is not necessarily the "best" value of $\lambda$. Other values of $\lambda$ may provide better results. For example, it may be better to use cross validation to find an optimal value for $\lambda$. We do not pursue alternative strategies for selecting $\lambda$ in this paper. We find that $\hat{\lambda}_{0}$ generally provides satisfactory results (see Sections 4 and 5). Moreover, computing $\hat{\lambda}_{0}$ is relatively computationally efficient, particularly when compared to methods such as cross validation.

We conclude this section with a discussion. We find the ridged inverse estimator of $\beta$ to be of theoretical interest. The inspiration for the estimator originated in the framework of the functional approach. In this context, the estimator derives from an application of ridge regression. But we have shown that the estimator can also be viewed as a GLS-like estimator, with a ridged estimate of the covariance matrix. In both cases, ridging is used to stabilize a noisy estimator. This link between the methods makes their equivalence seem quite natural. Nonetheless, we do not view this equivalence as entirely trivial or obvious. It is interesting to note, for example, that the matrices that are ridged $-\mathcal{P}_{c} \mathcal{P}_{c}^{\prime}$ in the case of the ridge regression, and $Y_{c} Y_{c}^{\prime}$ in the case of the GLS regression - are not even the same dimension.

Of course, ridge regression is not the only potential solution when $n_{c}$ is only slightly larger (or possibly even less) than $m$. Other dimensionality reduction strategies are possible as well. For example, principal components regression (PCR) is a common alternative (Friedman et al., 2009). We have shown that ridge regression leads to a GLS-like estimator. Does PCR lead to some other interesting estimator? Indeed it does - RUV-4! Strictly speaking, the equivalence is not exact, but it is close, especially in spirit. Let $\mathcal{P}=X_{\perp}^{\prime} Y$. To estimate $f$ by principal components regression, we take $\mathcal{P}_{c}$ and throw away all by the first $K$ right singular vectors of $\mathcal{P}_{c}$ to form a dimensionally-reduced set of predictors $\mathcal{P}_{c}^{(K)}$. We then regress $\mathcal{S}_{c}$ on $\mathcal{P}_{c}^{(K)}$ to estimate $f$, i.e. $\hat{f}(u)=\mathcal{S}_{c} \mathcal{P}_{c}^{(K) \prime}\left(\mathcal{P}_{c}^{(K)} \mathcal{P}_{c}^{(K) \prime}\right)^{-1} u$. With RUV-4, the basic idea is the same, except that we first calculate the first $K$ right singular vectors of $\mathcal{P}$ (instead of just $\mathcal{P}_{c}$ ) and only then restrict ourselves to the control genes.

Is there any reason to prefer ridge regression to PCR (or RUV-4 proper)? Arguably there is. We may prefer ridge regression to PCR for two reasons. The first reason is statistical in nature, and is that the dimensionality reduction of ridge regression is "softer" than that of PCR. See, e.g. Friedman et al. (2009) for further discussion. The second reason is computational. With ridge regression we are able to apply the inverse method for estimating variances and get an analytic solution for $\hat{\sigma}^{2}$ that is computationally efficient to compute. With PCR (or RUV-4 proper) we are still able to apply the inverse method, but we would need to do it numerically. We would need to generate a lot of random $X$ and calculate the resulting $\hat{\beta}^{\star}$ for each one. Each iteration would require computing a new singular value decomposition.

### 3.9.2 RUV-1

In Section 3.9.1 we found inspiration in the functional approach to develop RUV-rinv. Here we develop another technique inspired by the functional approach. Recall that RUV-4 (or RUV-inv) can be considered as a special case of the functional approach. We set $\mathcal{P}$ equal to $\hat{W}_{0}^{\prime} Y$ (or $X_{\perp}^{\prime} Y$ for RUV-inv), constrain $\hat{f}$ to be a linear function that passes through the origin, and fit by least squares. In Section 3.9.1 we modified this slightly to arrive at RUV-rinv; instead of fitting by least squares we fit by ridge regression. Here we make a different modification. We supplement $\mathcal{P}$ with additional predictors. We continue to constrain $\hat{f}$ to be a linear function that passes through the origin and fit by least squares.

Suppose $\eta$ is some $o \times n$ matrix of predictors, where $o \leq n_{c}-m+p$ (ideally, $o \ll n_{c}$ ). The rows of $\eta$ may contain, for example, information on the GC content of genes, the physical location of probes on the
microarray, etc. We set

$$
\mathcal{P}=\binom{\mathcal{A}}{\eta}
$$

where $\mathcal{A}$ denotes the original set of predictors, i.e. $\hat{W}_{0}^{\prime} Y$ in the case of RUV-4 or $X_{\perp}^{\prime} Y$ in the case of RUV-inv. We then estimate $\beta$ as

$$
\begin{equation*}
\hat{\beta}=\mathcal{S}-\mathcal{S}_{c} \mathcal{P}_{c}^{\prime}\left(\mathcal{P}_{c} \mathcal{P}_{c}^{\prime}\right)^{-1} \mathcal{P} \tag{214}
\end{equation*}
$$

Let us reformulate this estimator. Note that $\mathcal{S}_{c} \mathcal{P}_{c}^{\prime}\left(\mathcal{P}_{c} \mathcal{P}_{c}^{\prime}\right)^{-1}$ is a regression of $\mathcal{S}_{c}$ on $\mathcal{P}_{c}$. More specifically, it is a regression of $\mathcal{S}_{c}$ on $\mathcal{A}_{c}$ and $\eta_{c}$. We now use the fact that this is equivalent to a regression of $\mathcal{S}_{c}$ adjusted for $\eta_{c}$ on $\mathcal{A}_{c}$ adjusted for $\eta_{c}$. We define

$$
\begin{align*}
\tilde{\mathcal{S}} & \equiv \mathcal{S}-\mathcal{S}_{c} \eta_{c}^{\prime}\left(\eta_{c} \eta_{c}^{\prime}\right)^{-1} \eta  \tag{215}\\
\tilde{\mathcal{A}} & \equiv \mathcal{A}-\mathcal{A}_{c} \eta_{c}^{\prime}\left(\eta_{c} \eta_{c}^{\prime}\right)^{-1} \eta \tag{216}
\end{align*}
$$

We may now rewrite $\hat{\beta}$ as

$$
\begin{equation*}
\hat{\beta}=\tilde{\mathcal{S}}-\tilde{\mathcal{S}}_{c} \tilde{\mathcal{A}}_{c}^{\prime}\left(\tilde{\mathcal{A}}_{c} \tilde{\mathcal{A}}_{c}^{\prime}\right)^{-1} \tilde{\mathcal{A}} \tag{217}
\end{equation*}
$$

Now consider the case that $\mathcal{A}=X_{\perp}^{\prime} Y$. Then

$$
\begin{align*}
\tilde{\mathcal{A}} & =X_{\perp}^{\prime} Y-X_{\perp}^{\prime} Y_{c} \eta_{c}^{\prime}\left(\eta_{c} \eta_{c}^{\prime}\right)^{-1} \eta  \tag{218}\\
\tilde{\mathcal{A}} & =X_{\perp}^{\prime}\left[Y-Y_{c} \eta_{c}^{\prime}\left(\eta_{c} \eta_{c}^{\prime}\right)^{-1} \eta\right]  \tag{219}\\
\tilde{\mathcal{A}} & =X_{\perp}^{\prime} \tilde{Y} \tag{220}
\end{align*}
$$

and

$$
\begin{align*}
\tilde{\mathcal{S}} & =X^{\prime} Y-X^{\prime} Y_{c} \eta_{c}^{\prime}\left(\eta_{c} \eta_{c}^{\prime}\right)^{-1} \eta  \tag{221}\\
\tilde{\mathcal{S}} & =X^{\prime}\left[Y-Y_{c} \eta_{c}^{\prime}\left(\eta_{c} \eta_{c}^{\prime}\right)^{-1} \eta\right]  \tag{222}\\
\tilde{\mathcal{S}} & =X^{\prime} \tilde{Y} \tag{223}
\end{align*}
$$

where

$$
\begin{equation*}
\tilde{Y} \equiv Y-Y_{c} \eta_{c}^{\prime}\left(\eta_{c} \eta_{c}^{\prime}\right)^{-1} \eta \tag{224}
\end{equation*}
$$

We have arrived at the key result of this section. The functional approach estimate of $\beta$, constraining $\hat{f}$ to be a linear function that passes through the origin and fitting by least squares, and setting

$$
\mathcal{P}=\binom{X_{\perp}^{\prime} Y}{\eta}
$$

is equivalent to the RUV-inv estimate of $\beta$ using the adjusted dataset $\tilde{Y}$. This strongly suggests that adjusting $Y$ for $\eta$ to get $\tilde{Y}$ is a reasonable thing to do in and of itself. It may be regarded as a preprocessing step. We refer to this single step as RUV-1.

Let us examine RUV-1. Expression (224) resembles a residual operator. Indeed, if we limit our attention to the control genes, we see that

$$
\begin{align*}
\tilde{Y}_{c} & =Y_{c}-Y_{c} \eta_{c}^{\prime}\left(\eta_{c} \eta_{c}^{\prime}\right)^{-1} \eta_{c}  \tag{225}\\
& =Y_{c} R_{\eta_{c}^{\prime}} \tag{226}
\end{align*}
$$

where $R_{\eta_{c}^{\prime}}$ is the $n_{c} \times n_{c}$ residual operator of $\eta_{c}^{\prime}$. Note that $R_{\eta_{c}^{\prime}}$ is unlike other residual operators we have encountered so far. It is $n_{c} \times n_{c}$ instead of $m \times m$, and we use it to do projections on rows, not columns. In
words, we remove any patterns of gene-to-gene expression from the negative controls that resemble the rows of $\eta_{c}$.

Now define the matrix $c$ as the $n \times n_{c}$ matrix whose $(i, j)^{\text {th }}$ entry is 1 if $i$ is the index of the $j^{\text {th }}$ control gene and 0 otherwise. Thus $Y_{c}=Y c, \beta_{c}=\beta c$, etc. We may rewrite (224) as

$$
\begin{align*}
\tilde{Y} & \equiv Y-Y c \eta_{c}^{\prime}\left(\eta_{c} \eta_{c}^{\prime}\right)^{-1} \eta  \tag{227}\\
& =Y\left[I-c \eta_{c}^{\prime}\left(\eta_{c} \eta_{c}^{\prime}\right)^{-1} \eta\right] \tag{228}
\end{align*}
$$

and we refer to $\left[I-c \eta_{c}^{\prime}\left(\eta_{c} \eta_{c}^{\prime}\right)^{-1} \eta\right]$ as the RUV-1 operator. We find it helpful to think of the RUV-1 operator as an "extrapolated residual operator." For each sample $i$, a linear combination of $\eta_{c}$ is subtracted off from $Y_{i c}$ so that $\tilde{Y}_{i c}$ is orthogonal to $\eta_{c}$. This same linear combination is then applied to $\eta$ as a whole, and subtracted off of the other genes as well.

Let us now consider RUV-1 in the context of a model similar to that of Section 3.1. We model $Y$ as

$$
\begin{equation*}
Y=X \beta+Z \gamma+W \alpha+T \eta+\epsilon \tag{229}
\end{equation*}
$$

where $T$ is unobserved but $\eta$ is observed. Suppose we apply RUV-1. Then

$$
\begin{equation*}
\tilde{Y}=(X \beta+Z \gamma+W \alpha+T \eta+\epsilon)\left[I-c \eta_{c}^{\prime}\left(\eta_{c} \eta_{c}^{\prime}\right)^{-1} \eta\right] \tag{230}
\end{equation*}
$$

But

$$
\begin{equation*}
T \eta\left[I-c \eta_{c}^{\prime}\left(\eta_{c} \eta_{c}^{\prime}\right)^{-1} \eta\right]=0 \tag{231}
\end{equation*}
$$

and, assuming $\beta_{c} \eta_{c}^{\prime}=0$,

$$
\begin{equation*}
X \beta\left[I-c \eta_{c}^{\prime}\left(\eta_{c} \eta_{c}^{\prime}\right)^{-1} \eta\right]=X \beta \tag{232}
\end{equation*}
$$

so (230) simplifies to

$$
\begin{equation*}
\tilde{Y}=X \beta+(Z \gamma+W \alpha+\epsilon)\left[I-c \eta_{c}^{\prime}\left(\eta_{c} \eta_{c}^{\prime}\right)^{-1} \eta\right] . \tag{233}
\end{equation*}
$$

If we then premultiply by $Z_{\perp}^{\prime}$ as in Section 3.6.2, we are left with

$$
\begin{equation*}
Z_{\perp}^{\prime} \tilde{Y}=Z_{\perp}^{\prime} X \beta+Z_{\perp}^{\prime} W \alpha\left[I-c \eta_{c}^{\prime}\left(\eta_{c} \eta_{c}^{\prime}\right)^{-1} \eta\right]+\epsilon-\epsilon_{c} \eta_{c}^{\prime}\left(\eta_{c} \eta_{c}^{\prime}\right)^{-1} \eta \tag{234}
\end{equation*}
$$

Note that $\epsilon_{c}^{\prime}$ is approximately orthogonal to $\eta_{c}^{\prime}$ and $\epsilon_{c} \eta_{c}^{\prime}\left(\eta_{c} \eta_{c}^{\prime}\right)^{-1} \approx 0$ with high probability, so we may disregard the last term. Thus, we are back in a very familiar setting. The only thing new is that $\alpha$ has been replaced with $\alpha\left[I-c \eta_{c}^{\prime}\left(\eta_{c} \eta_{c}^{\prime}\right)^{-1} \eta\right]$. Since $\alpha$ is unobserved to begin with, this hardly changes things from a practical point of view. Having applied RUV-1, we may now proceed with any of our other analyses just as before.

We do not actually apply RUV-1 in any of the examples of this paper. To do so we would need to identify good variables to include in $\eta$, and we have not yet had the opportunity to research this fully. We have included the discussion in this section mainly out of theoretical interest, and because we believe RUV-1 will indeed prove useful with some forms of high dimensional data (though perhaps not microarray data).

We conclude with a discussion of a special case of RUV-1. Let $\eta=\mathbf{1}$, where $\mathbf{1} \equiv 1_{1 \times n}$ is a row vector of ones. The RUV-1 operator simplifies to

$$
I-\frac{c \mathbf{1}_{c}^{\prime} \mathbf{1}}{n_{c}}
$$

and RUV-1 amounts to setting

$$
\tilde{Y}_{i \star}=Y_{i \star}-\bar{Y}_{i c} \mathbf{1}
$$

In words, we subtract off from each sample the average value of the control genes for that sample.
The idea of subtracting off the mean of each sample's control genes is simple and appealing. It is also the starting point for other ideas. For example, in addition to mean-shifting each sample so that the controls
have mean 0 , we might also wish to rescale each sample so that the standard deviation of the control genes is equal to 1 (or some other number). Taking this idea even further, we might wish to warp the observed distribution of each sample so that the distribution of the negative controls remains fixed. We do not pursue this line of thought any further, but the interested reader may wish to consult Wu and Aryee (2010).

Finally, we consider the case $\eta=\mathbf{1}$ in the context of the functional approach. In the context of the functional approach, setting $\eta=\mathbf{1}$ is equivalent to allowing $\hat{f}$ to have an intercept. Is there any advantage to allowing $\hat{f}$ to have an intercept? Once again, we consider an example in which $m=2$ and $k=1$, as in Section 3.4. Once again, the $\alpha_{j}$ are independent and normally distributed. However, now the expectation of $\alpha_{j}$ is non-zero. This example is plotted in Figure 9. The orange line is forced through the origin. The red line is allowed to have an intercept. We prefer the red line to the orange line.

Might we expect to encounter $\alpha_{j}$ with non-zero expectation in practice? Yes and no. Intuitively, we would certainly expect such $\alpha_{j}$ to exist. Consider scanner sensitivity as a possible source of unwanted variation. A more sensitive scanner would presumably raise the observed expression level of every gene. Every $\alpha_{j}$ would be positive. However, with microarray data, this is almost never an issue in practice. The reason is preprocessing. Quantile normalization effectively fixes the mean of each array to be identical. In most cases, this fixes the mean of the control genes of each array to be nearly identical as well. For all practical purposes, it is as if RUV-1 with $\eta=\mathbf{1}$ has already been applied. Thus, in the microarray world, RUV-1 with $\eta=\mathbf{1}$ is of limited utility. Nonetheless, we suspect there are examples with other types of high dimensional data where RUV-1 with $\eta=\mathbf{1}$ is useful.

Figure 9: An example in which the expectation of $\alpha_{j}$ is non-zero.

### 3.9.3 Empirical Controls

In many cases, a researcher will know a priori that $\beta_{j}=0$ for many $j$, but not know the specific $j$ for which $\beta_{j}=0$. The researcher would like to discover the $j$ for which $\beta_{j}=0$. She may then use these genes as "empirical" control genes. Discovering empirical controls is often feasible, but may require some care. In this section we comment briefly on the strategy of empirical controls.

There is no single method for discovering empirical controls. This is why we refer simply to the "strategy" of empirical controls. Nonetheless, we might describe a typical application of the strategy of empirical controls as follows: First, a researcher designates an initial set of control genes. She then applies an initial analysis, such as RUV-4. Finally, she notes which genes are found to be significantly associated with $X$ at some false discovery rate (FDR) and designates all other (insignificant) genes as empirical negative controls. The initial set of negative controls and the initial method of analysis are left to the discretion of the researcher. However, even this "typical application" is not set in stone. For example, a researcher may fear that her $p$ values are biased (either systematically inflated or deflated) and not trust the FDR. However, if she believes, for example, that no more than 100 entries of $\beta$ are non-zero, she may simply rank the genes by $p$-value and designate all but the top 100 as empirical negative controls.

The strategy of empirical controls can be iterated. For example, a researcher may begin with an initial set of control genes, generate a set of empirical controls, and then use this set of empirical controls to produce a refined set of empirical controls. A related point is that the initial (non-empirical) set of control genes need not be a "perfect" set of control genes. RUV-4 is relatively insensitive to violations of the control gene assumption, and it is often OK to include a few genes $j$ such that $\beta_{j} \neq 0$ in the initial set of control genes. For example, if $\beta$ is known to be sparse, it is often satisfactory to use all genes as an initial set of control genes. This fact is particularly useful when it is known that $\beta$ is sparse, but nothing at all is known about which entries of $\beta$ are non-zero.

Note that the strategy of empirical controls is much "safer" with RUV-4 than it is with RUV-2. The reason is that RUV-4 is less sensitive to violations of the control gene assumption. Consider a typical application of the strategy of empirical controls as described above. It is very unlikely that the initial analysis will properly identify all differentially expressed genes. The resulting set of empirical controls will very likely contain genes $j$ such that $\beta_{j} \neq 0$. With RUV-2, this may be a serious problem. With RUV-4 it often is not.

Nonetheless, we recommend that a researcher who chooses to pursue the strategy of empirical controls do so with particular care. We are unaware of any argument that would guarantee that the strategy of empirical controls will always lead to better results. We therefore recommend that a researcher pause to inspect her set of empirical controls, and ensure that they seem reasonable. If a researcher chooses to iterate the strategy of empirical controls, we recommend that she pause and inspect her empirical controls after each iteration. Presumably only a very small number if iterations will be required; if the set of empirical controls keeps changing substantially with each iteration, this may be a sign that something is wrong. Similarly, we recommend that the researcher evaluate the quality of the initial analysis itself. Gene rankings, $p$-value histograms, and projection plots (see Section 5) are all helpful.

The initial analysis does not need to be perfect. The goal of the initial analysis is only to produce a set of empirical controls that is better than the set of initial controls. This has implications for the choice of method (and tuning parameters) in the initial analysis. Consider a simple example. Suppose that $\beta$ is known to be sparse, but nothing is known about which elements of $\beta$ are non-zero. A researcher may choose to include all genes in the set of initial controls. Suppose that some of the non-zero elements of $\beta$ are quite large. Even though RUV-4 is relatively insensitive to violations of the control gene assumption, including genes with large $\beta_{j}$ in the set of control genes may cause serious problems, particularly when $K$ is large. The researcher may therefore choose to avoid RUV-inv, stick to RUV-4, and choose an appropriate, relatively small $K$ "by hand," i.e. choose $K$ based on $p$-value histograms, projection plots, etc. Using this approach, the very large entries of $\beta$ can be reliably identified and discarded from the set of control genes. It may then be safe to pursue a second iteration of the strategy of empirical controls. In the second iteration, a larger value of $K$, or even RUV-inv may be appropriate.

Finally, note that the "typical" application of the strategy of empirical controls described above relies on an accurate estimation of the FDR. For this reason, it is important that the method used for the initial analysis exhibit good control of the type 1 error rate. If the method is too conservative, some genes that are actually differentially expressed will not appear to be differentially expressed. These genes will be improperly included in the set of empirical controls. If the method is anti-conservative, many genes that are not actually differentially expressed will appear to be differentially expressed. These genes will be improperly excluded
from the set of empirical controls. The ability of a method to properly control the type 1 error rate is therefore an important consideration to keep in mind when selecting the method to be used in the initial analysis. In Sections 4 and 5 we see that RUV-rinv is often a suitable choice. Another possibility is to use either the method of rescaled variances or the method of empirical variances. These methods are the subject of the next section.

### 3.9.4 Rescaled and Empirical Variances

In Section 3.6.1 we define

$$
\begin{equation*}
\widehat{\operatorname{Var}}\left[\hat{\beta}_{j_{\bar{c}}} \mid \alpha_{\star j_{\bar{c}}}\right] \equiv\left(1+\hat{b}_{W X} \hat{b}_{W X}^{\prime}\right) \hat{\sigma}_{j_{\bar{c}}}^{2} \tag{235}
\end{equation*}
$$

In other words, conditional on $\hat{b}_{W X}$, we estimate the conditional variance of $\hat{\beta}_{j_{\bar{c}}}$ by multiplying $\hat{\sigma}_{j_{\bar{c}}}^{2}$ by a fixed constant. In Section 3.6 .5 we note that, given a poor choice of $K$, the $\hat{\sigma}_{j}^{2}$ may be either systematically too large or too small. As a result, the type 1 error rate may be wrong. We now propose a different estimate of $\operatorname{Var}\left[\hat{\beta}_{j_{\bar{c}}} \mid \alpha_{\star j_{\bar{c}}}\right]$. Let

$$
\begin{equation*}
\widehat{\operatorname{Var}}^{(\mathrm{rs})}\left[\hat{\beta}_{j_{\bar{c}}} \mid \alpha_{\star j_{\bar{c}}}\right] \equiv\left(\frac{1}{n_{c}} \sum_{j_{c}} \frac{\hat{\beta}_{j_{c}}^{2}}{\hat{\sigma}_{j_{c}}^{2}}\right) \hat{\sigma}_{j_{\bar{c}}}^{2} \tag{236}
\end{equation*}
$$

We name this the "rescaled" estimate of the variance. Just as in (235), we estimate the conditional variance of $\hat{\beta}_{j_{\bar{c}}}$ by multiplying $\hat{\sigma}_{j_{\bar{c}}}^{2}$ by a fixed constant. However, in (236) we ignore the theory and simply use the control genes to figure out what the constant "should" be.

Note that $\widehat{\operatorname{Var}}\left[\hat{\beta}_{\bar{c}}\right]$ and $\widehat{\operatorname{Var}}^{(\mathrm{rs})}\left[\hat{\beta}_{j_{\bar{c}}} \mid \alpha_{\star j_{\bar{c}}}\right]$ differ only by a fixed constant factor. Thus, $t$-statistics calculated using rescaled variances will also differ from standard $t$-statistics only by a fixed constant factor. In particular, the ordering of the $t$-statistics will be unaffected, as will the ordering of the $p$-values.

More generally, we might consider estimates of the form

$$
\begin{equation*}
\widehat{\operatorname{Var}}^{(\mathrm{emp})}\left[\hat{\beta}_{j_{\bar{c}}} \mid \alpha_{\star j_{\bar{c}}}\right] \equiv \hat{g}\left(\hat{\sigma}_{j_{\bar{c}}}^{2}\right) \tag{237}
\end{equation*}
$$

for some function $\hat{g}$. If we set $\hat{g}(u)=\left(1+\hat{b}_{W X} \hat{b}_{W X}^{\prime}\right) u$ we recover (235); if we set $\hat{g}(u)=\left(\frac{1}{n_{c}} \sum_{j_{c}} \hat{\beta}_{j_{c}}^{2} / \hat{\sigma}_{j_{c}}^{2}\right) u$ we recover (236). In general, however, we need not restrict $\hat{g}$ to be a linear, or even parametric, function. If a large proportion of genes are control genes (e.g. empirical controls) it may be possible to fit a nonparametric function $\hat{g}$ to the $\left(\hat{\sigma}_{j_{c}}^{2}, \hat{\beta}_{j_{c}}^{2}\right)$ pairs. Alternatively, if we do not have many control genes but believe that $\beta$ is sparse, it may be possible to fit a nonparametric function $\hat{g}$ to the pairs $\left(\hat{\sigma}_{j}^{2}, \hat{\beta}_{j}^{2}\right)$ using some form of robust regression that ignores outliers. We refer to such methods generically as "the method of empirical variances." We will now discuss one such method in particular.

We begin by re-indexing the genes. We re-order the genes in order of increasing $\hat{\sigma}^{2}$ and then bin the genes into $B$ bins of size $S$ (the final bin may be smaller than $S$; we ignore this minor complication and assume $n=B \times S)$. We then index genes by bin and number within bin, so that $\hat{\sigma}_{b, s}^{2}$ is the $s^{\text {th }}$ gene in bin b. Note that $\hat{\sigma}_{b, s}^{2} \leq \hat{\sigma}_{b^{\prime}, s^{\prime}}^{2}$ if $b<b^{\prime}$ and that $\hat{\sigma}_{b, s}^{2} \leq \hat{\sigma}_{b, s^{\prime}}^{2}$ if $s<s^{\prime}$.

Let

$$
\begin{equation*}
s^{\star}(b) \equiv \underset{s}{\operatorname{argmax}} \hat{\beta}_{b, s}^{2} \tag{238}
\end{equation*}
$$

For each $b$, remove the $\left(b, s^{\star}(b)\right)^{\text {th }}$ gene from the dataset. We may view the removal of these genes as the removal of potential outliers. Alternatively, we may think of the remaining $B(S-1)$ genes as a set of empirical controls. Now use some form of non-parametric regression to fit a function $\hat{g}_{0}$ to the $\left(\hat{\sigma}_{b, s}^{2}, \hat{\beta}_{b, s}^{2}\right)$ pairs of the remaining $B(S-1)$ genes.

We do not want to set $\hat{g}=\hat{g}_{0} . \hat{g}_{0}$ is too small, because we have systematically removed from the dataset the genes with the largest values of $\hat{\beta}_{b, s}^{2}$. To fix this problem we set

$$
\begin{equation*}
\hat{g}=\nu \hat{g}_{0} \tag{239}
\end{equation*}
$$

for some value of $\nu$. We choose to set

$$
\begin{equation*}
\nu^{-1}=\mathbb{E}\left[\frac{1}{S-1} \sum_{t \neq t^{\star}} \chi_{t}^{2}\right] \tag{240}
\end{equation*}
$$

where $t$ ranges from 1 to $S$, the $\chi_{t}^{2}$ are IID and follow a $\chi^{2}$ distribution with 1 degree of freedom, and $t^{\star}=\operatorname{argmax} \chi_{t}^{2}$.

In all of the examples of this paper we set $S=10$. This is arbitrary. Other values of $S$ may perform better. In particular, one may wish to choose $S$ based on the degree of sparsity of $\beta$. For the non-parametric regression, we choose to use the minimum lower sets algorithm (Wright, 1978; Barlow et al., 1972). This method restricts $\hat{g}_{0}$ to be a non-decreasing function, but otherwise imposes few constraints on $\hat{g}_{0}$. We choose this method for its relative simplicity; one nice feature of the minimum lower sets algorithm is that it does not require us to set a bandwidth parameter. Other non-parametric regression methods may perform better.

## 4 Simulation Results

In this section we use simulated data to explore the performance of the various RUV methods. In Section 4.1 we outline the process we use to simulate the data. In Section 4.2 we compare the performance of RUV-2, RUV-4, and "vanilla" RUV-inv. We find that RUV-4 generally outperforms RUV-2, and that RUV-inv generally performs as well as RUV-4 at the optimal value of $K$. In Section 4.3 we compare the several variants of RUV-inv, both to one another and to SVA, LEAPP, and ICE. ${ }^{3}$

### 4.1 The Simulated Data

In all simulations we set $m=50$ and $n=10000$. We designate $n_{c}$ genes as control genes. The value of $n_{c}$ is specified separately for each simulation. In some simulations, the control genes are true negative controls, i.e. $\beta_{c}=0$. In others, the "control genes" have been misspecified and $\beta_{c} \neq 0$. Note that when we refer to "control genes," we refer to these genes that have been designated as negative controls, whether or not $\beta_{c}=0$. Conversely, we refer to a gene $j$ as a "true negative control" if $\beta_{j}=0$, whether or not we have designated gene $j$ to be used as control gene.

We generate the simulation data as follows:

- $X$ is chosen uniformly at random from the unit $m-1$ sphere.
- Each column of $W_{0}$ is chosen uniformly at random from the unit $m-2$ sphere lying in the orthogonal complement of $\mathfrak{R}(X)$. Each column of $W_{0}$ is chosen independently of the others, and thus the columns of $W_{0}$ are not exactly orthogonal. $W$ is then set equal to $W_{0}+X b_{W X} . b_{W X}$ is specified separately for each simulation.
- Some entries of $\beta$ are set equal to 0 . Which entries of $\beta$ are set equal to 0 is specified separately for each simulation. Non-zero entries of $\beta$ are IID standard normal.
- The entries of $\alpha$ are independent and normally distributed with mean 0 . The variance of $\alpha_{i j}$ depends only on the row $i$. Denote the variance of row $i$ by $\sigma_{\alpha, i}^{2}$ and denote $\sigma_{\alpha} \equiv\left(\sigma_{\alpha, 1}, \ldots, \sigma_{\alpha, k}\right)$. Note that $\sigma_{\alpha}$ specifies the square roots of the variances, not the variances themselves.

[^3]- The individual gene variances $\sigma_{j}^{2}$ (not to be confused with the $\sigma_{\alpha, i}^{2}$ ) are IID and distributed as $(0.025 S+$ $.025)^{2}$, where $S \sim \operatorname{Exp}(1)$. This distribution roughly approximates empirical distributions of $\sigma_{j}^{2}$ that we have observed in real data.
- The $\epsilon_{i j}$ are independent and normally distributed with mean 0 and variance $\sigma_{j}^{2}$.
- Finally, we set $Y=X \beta+W \alpha+\epsilon$.

Note that the key parameters that vary from one simulation to the next are: $k, b_{W X}, \sigma_{\alpha}$, which entries of $\beta$ equal 0 , and which genes are designated as controls.

### 4.2 RUV-2 vs. RUV-4 vs. RUV-inv

In this section we run 12 simulations and compare the relative performance of RUV-2, RUV-4, and RUV-inv. First we discuss the details of the simulations. Then we discuss the results of one of the 12 simulations in detail. Finally we discuss briefly the results of the remaining 11 simulations.

### 4.2.1 Simulation Details

In each simulation we set $n_{c}=1000$. In six of the simulations ("good controls"), $\beta_{1 j}=0$ for every control gene. In the other six simulations ("bad controls"), $\beta_{1 j}=0$ for only 900 of the 1000 control genes.

In the first four simulations $k=20$ and

$$
\begin{equation*}
\sigma_{\alpha}=(1.1,1.0,0.8,0.5,0.4,0.4,0.3,0.3,0.2,0.2, .16, .16, .15, .15, .14, .13, .13, .12, .12, .11) \tag{241}
\end{equation*}
$$

This value of $\sigma_{\alpha}$ is similar to what we observe empirically in the gender dataset. In the first two simulations ("lightly correlated") $b_{W X}=(.1, \ldots, .1)$ and in the second two simulations ("moderately correlated") $b_{W X}=$ $(.4, .4, .4, .2, \ldots, .2)$. Note that in the "moderately correlated" case the columns of $W$ that are most highly correlated with $X$ correspond to the rows of $\alpha$ with the largest $\sigma_{\alpha, i}$. In other words, the biggest unwanted factors are also the most correlated with $X$.

The next four simulations are "harder." In these simulations ("moderate decay") $k=70$ and $\sigma_{\alpha}=$ $(1,1 / 2, \ldots, 1 / 70)$. Note in particular that $k=70>m=50$. In two of the simulations ("lightly correlated") $b_{W X}=(.1, \ldots, .1)$ as before. In the other two simulations ("highly correlated") the elements of $b_{W X}$ are chosen uniformly at random from ( $-1,1$ ). The final four simulations ("slow decay") are "harder" still. These simulations are identical to the previous four, but now $\sigma_{\alpha}=(1,1 / \sqrt{2}, \ldots, 1 / \sqrt{70})$.

For all 12 simulations we generate 1000 datasets. We fit each dataset by RUV-2, RUV-4, and RUV-inv. In the case of RUV-2 and RUV-4, we fit with each value of $K$ from 1 to 47 . We also fit each dataset using a standard linear model that contained only an $X$ term (the "unadjusted" case). All of our models include an intercept, i.e. a $Z=1_{m \times 1}$ term. We fit all models both with and without Limma (Smyth, 2004).

For every model fit we record the following six quality metrics: (1) the fraction of the 100 genes with the largest values of $\beta_{1 j}^{2} / \sigma_{j}^{2}$ that end up being ranked as one of the top 100 most significantly DE genes ("top ranked fraction"), (2) the fraction of genes with $\beta_{1 j}=0$ to have a $p$-value less than 0.05 ("type 1 error rate"), (3) the fraction of genes with $\beta_{1 j} \neq 0$ to have a $p$-value less than 0.05 ("average power"), (4) the RMSE of $\hat{\beta}$ ("beta hat RMSE"), (5) the log of the mean value of $\hat{\sigma}_{j}^{2} / \sigma_{j}^{2}$ ("sigma hat scale"), (6) the IQR of $\log \left(\hat{\sigma}_{j}^{2} / \sigma_{j}^{2}\right)$ ("rescaled sigma hat IQR"). Of these six quality metrics, the first is arguably the most important. In practice, the goal of a DE study is usually to produce a list of genes that are "most interesting" and warrant further study. We will refer to the ability of a method to properly rank top genes as "discriminative power."

### 4.2.2 Results of " $k=20$, moderately correlated, good controls"

We plotted the average value (over the 1000 datasets) of each of the six quality metrics. See Figure 10 and Figures $15-26$ in the SM. The results for RUV-2 (brown) and RUV-4 (orange) are shown as a function of $K$. The results for RUV-inv (blue) and the unadjusted case (black) are shown by horizontal lines. Solid lines are
for "standard" estimates of $\sigma^{2}$ and dashed lines are for estimates using Limma. The light dotted lines show $95 \%$ nominal confidence intervals; these are not always visible as the confidence intervals are quite small.

Figure 10: Moderately correlated, good controls.
In this section we focus on Figure 10 (" $k=20$, moderately correlated, good controls"). The first thing to notice is that RUV-inv performs very well. In terms of discriminative power, RUV-inv performs about as well as RUV-2 and RUV-4 at the optimal value of $K$. The type 1 error rate for RUV-inv is very close to 0.05 (see also Tables 4, 5, 6 in the SM). By comparison, RUV-2 is anti-conservative when $K<20$ and RUV-4 is anti-conservative for all $K$.

RUV-inv also performs well in terms of its estimation of $\beta$ and $\sigma^{2}$. As expected, the RMSE of $\hat{\beta}$ is effectively nonincreasing in $K$ for RUV-4 but not RUV-2. RUV-inv essentially achieves the minimum RMSE. Also as expected, both RUV-2 and RUV-4 have seriously inflated estimates of $\sigma^{2}$ when $K<20$. When $K>20$ RUV-4 has slightly deflated estimates of $\sigma^{2}$, but RUV-2 is nearly spot-on. RUV-inv has slightly inflated estimates of $\sigma^{2}$. The average value of $\hat{\sigma}_{j}^{2} / \sigma_{j}^{2}$ is about 1.16 (see also Tables $4,5,6$ in the SM). Nonetheless, these slightly inflated estimates of $\sigma^{2}$ do not cause an unreasonable loss in power.

Indeed, the slightly inflated RUV-inv estimates of $\sigma^{2}$ are both expected and desirable. Recall that $\hat{\beta}$ is slightly biased. Recall also that $\sigma^{2}$ is estimated under the assumption that $\hat{\beta}^{\star}$ is unbiased. Therefore it is reasonable to expect that $\hat{\sigma}^{2}$ will be slightly inflated due to the biases of $\hat{\beta}^{\star}$. The end result is that we essentially fold the small biases of $\hat{\beta}^{\star}$ into the estimate $\hat{\sigma}^{2}$, and thereby keep the type 1 error rate in check. Of course, there is no guarantee that the type 1 error rate will equal 0.05 in all situations. Nonetheless, the inflated estimates of $\sigma^{2}$ are often a useful feature in practice. Finally, note that RUV-inv achieves a nearly optimal value of IQR $\left[\log \left(\hat{\sigma}_{j}^{2} / \sigma_{j}^{2}\right)\right]$, suggesting that RUV-inv makes good use of all the degrees of freedom that are available to estimate $\sigma^{2}$.

An interesting conclusion of Figure 10 seems to be that the primary determinant of the discriminative
power is the quality of the estimate of $\sigma^{2}$, and not the quality of the estimate of $\beta$. We arrive at this conclusion by noting several facts. First, note that although the RMSE $(\hat{\beta})$ curves for RUV-2 and RUV-4 diverge substantially for $K>20$, the curves for the discriminative power of RUV-2 and RUV-4 without Limma (solid lines) follow each other very closely. This suggests that the quality of $\hat{\beta}$ is not the main determinant of the discriminative power. Secondly, note that the discriminative power is substantially higher when we use Limma (dashed lines). This suggests that the quality of $\hat{\sigma}^{2}$ is important. Moreover, the improvement in discriminative power offered by Limma is largest when $K$ is large, where the quality of $\hat{\sigma}^{2}$ is poorest. Even more tellingly, the curves for the discriminative power of RUV-2 and RUV-4 with Limma do diverge for large $K$; once the problem of the poor estimates of $\sigma^{2}$ at large $K$ has been "solved" by Limma, it becomes possible to see the difference between the performance of $\hat{\beta}^{(R U V-2)}$ and $\hat{\beta}^{(R U V-4)}$. Finally, we observe that the the "kinks" in the discriminative power curves at $K=20$ are very similar to the kinks in the curves of the IQR of $\log \left(\hat{\sigma}_{j}^{2} / \sigma_{j}^{2}\right)$. Indeed, the entire discriminative power curve is visually similar to the $\operatorname{IQR}\left[\log \left(\hat{\sigma}_{j}^{2} / \sigma_{j}^{2}\right)\right]$ curve, just upside down.

### 4.2.3 Results of the Remaining Simulations

Turning now to the other 11 simulations (see Figures $15-26$ in the SM), we see that many, but not all, of the conclusions of Figure 10 are true more generally. In terms of discriminative power, RUV-4 performs almost uniformly better than RUV-2, and RUV-inv performs about as well as RUV-4 at the optimal value for $K$. The RMSE of $\hat{\beta}$ falls then rises again for RUV-2, but is essentially nonincreasing for RUV-4. RUV-4 is often anti-conservative, sometimes substantially. With RUV-2, the type 1 error rate is good for large $K$, but this is a moot point because the discriminative power of RUV-2 is poor at large $K$. For small $K$, the type 1 error rate can exhibit strange behavior in both RUV-2 and RUV-4. RUV-inv generally exhibits better control of the type 1 error rate than RUV-4, but is not perfect. RUV-inv tends to be anti-conservative when the unwanted factors are strongly correlated with factor of interest, and, to a lesser extent, when the control genes are misspecified. RUV-inv does a fairly good job of estimating $\sigma^{2}$ when $k=20$. Not surprisingly, no method does a particularly good job of estimating $\sigma^{2}$ when $k=70>m$.

We also see in the other simulations the effects of misspecified control genes. To a large extent, the "bad controls" do not affect RUV-4 or RUV-inv. RUV-2, by contrast, is very sensitive to the control gene assumption. The performance of $\hat{\beta}^{(R U V-2)}$ deteriorates considerably when the control genes are misspecified. This has serious consequences for both the discriminative power and type 1 error rate. Moreover, the consequences are not entirely predictable. Both the discriminative power and type 1 error rate may be complicated functions of $K$. See, for example, Figures 16 and 18.

### 4.3 A Comparison of Methods

In this Section we run 24 simulations to compare the relative performance of SVA, LEAPP, ICE, RUV-4, and RUV-(r)inv and their variants (empirical controls, rescaled variances, empirical variances). First we discuss the details of the simulations. Then we discuss the results of one of the 24 simulations in detail. Finally we discuss briefly the results of the remaining 23 simulations.

### 4.3.1 Simulation Details

The simulations of this section are similar to those of Section 4.2. In 12 of the simulations, $k=20$ and $\sigma_{\alpha}$ is set as in (241). In the other 12 simulations $k=70$ and $\sigma_{\alpha}$ is set as in "moderate decay." In 12 of the simulations $b_{W X}$ is set as in "lightly correlated" and in the other 12 as in "highly correlated." In all of the simulations all of the control genes are good controls, but in 12 of the simulations $n_{c}=1000$ and in the other 12 simulations $n_{c}=60$.

Unlike Section 4.2, here we also vary the sparsity of $\beta$. In eight of the simulations ("very sparse"), only 100 elements of $\beta$ are non-zero. In another eight simulations ("sparse") only 500 elements of $\beta$ are non-zero. In the remaining eight simulations ("not sparse") 5000 elements of $\beta$ are non-zero. There are a few other minor differences as well. We generated only 100 datasets per simulation instead of 1000 . We did not fit
with Limma. We report the mean value of $\hat{\sigma}_{j}^{2} / \sigma_{j}^{2}$ directly (instead of the log). We report only the results of RUV-4 for $\hat{k}$ and not all values of $K$. In some of the methods we make use of empirical controls. We define empirical controls to be all genes whose RUV-rinv FDR-adjusted $p$-values is greater that 0.5 .

Note that we do not report the results of $\operatorname{RMSE}(\hat{\beta}), \operatorname{AVG}\left(\hat{\sigma}_{j}^{2} / \sigma_{j}^{2}\right)$, or $\operatorname{IQR}\left[\log \left(\hat{\sigma}_{j}^{2} / \sigma_{j}^{2}\right)\right]$ for the rescaled variances or empirical variances methods, since these results are identical to those of the standard method. We also do not report $\operatorname{AVG}\left(\hat{\sigma}_{j}^{2} / \sigma_{j}^{2}\right)$ or $\operatorname{IQR}\left[\log \left(\hat{\sigma}_{j}^{2} / \sigma_{j}^{2}\right)\right]$ for ICE, since ICE, which is based on a random effects model, does not return an estimate of the equivalent of the $\sigma^{2}$ that exists in our model.

### 4.3.2 $k=20$, moderately correlated, $n_{c}=60$, sparse

As in the Section 4.2, we discuss the results of just one of the simulations in detail. We present the results of the other simulations in the Supplementary Material. The simulation we discuss in detail is " $k=20$, moderately correlated, $n_{c}=60$, sparse". The results of this simulation are given in Table 2.

|  | Top Rank Frac. |  | Type 1 |  | Average Power |  | $\operatorname{RMSE}(\hat{\beta})$ |  | $\operatorname{AVG}\left(\hat{\sigma}_{j}^{2} / \sigma_{j}^{2}\right)$ |  | $\operatorname{IQR}\left[\log \left(\hat{\sigma}_{j}^{2} / \sigma_{j}^{2}\right)\right]$ |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| Unadjusted | 0.52 | $\left(4 \times 10^{-3}\right)$ | 0.47 | $\left(5 \times 10^{-4}\right)$ | 0.66 | $\left(2 \times 10^{-3}\right)$ | 0.707 | $\left(5 \times 10^{-4}\right)$ | 53.02 | $\left(5 \times 10^{-2}\right)$ | 1.41 | $\left(2 \times 10^{-3}\right)$ |
| SVA (IRW) | 0.72 | $\left(4 \times 10^{-3}\right)$ | 0.10 | $\left(5 \times 10^{-3}\right)$ | 0.78 | $\left(2 \times 10^{-3}\right)$ | 0.170 | $\left(3 \times 10^{-3}\right)$ | 6.08 | $\left(7 \times 10^{-2}\right)$ | 1.06 | $\left(3 \times 10^{-3}\right)$ |
| SVA (2-step) | 0.72 | $\left(4 \times 10^{-3}\right)$ | 0.11 | $\left(5 \times 10^{-3}\right)$ | 0.80 | $\left(2 \times 10^{-3}\right)$ | 0.163 | $\left(3 \times 10^{-3}\right)$ | 6.03 | $\left(7 \times 10^{-2}\right)$ | 1.05 | $\left(4 \times 10^{-3}\right)$ |
| LEAPP | 0.72 | $\left(4 \times 10^{-3}\right)$ | 0.26 | $\left(8 \times 10^{-3}\right)$ | 0.86 | $\left(2 \times 10^{-3}\right)$ | 0.133 | $\left(2 \times 10^{-3}\right)$ | 5.22 | $\left(7 \times 10^{-2}\right)$ | 1.06 | $\left(3 \times 10^{-3}\right)$ |
| ICE | 0.80 | $\left(2 \times 10^{-3}\right)$ | 0.00 | $\left(4 \times 10^{-5}\right)$ | 0.72 | $\left(2 \times 10^{-3}\right)$ | 0.091 | $\left(6 \times 10^{-4}\right)$ |  |  |  |  |
| RUV-4 | 0.78 | $\left(1 \times 10^{-2}\right)$ | 0.12 | $\left(3 \times 10^{-3}\right)$ | 0.80 | $\left(7 \times 10^{-3}\right)$ | 0.151 | $\left(3 \times 10^{-3}\right)$ | 0.96 | $\left(1 \times 10^{-3}\right)$ | 0.73 | $\left(3 \times 10^{-2}\right)$ |
| RUV-inv | 0.72 | $\left(4 \times 10^{-3}\right)$ | 0.02 | $\left(1 \times 10^{-3}\right)$ | 0.62 | $\left(1 \times 10^{-2}\right)$ | 0.209 | $\left(5 \times 10^{-3}\right)$ | 1.57 | $\left(1 \times 10^{-2}\right)$ | 1.01 | $\left(1 \times 10^{-2}\right)$ |
| RUV-rinv | 0.82 | $\left(3 \times 10^{-3}\right)$ | 0.06 | $\left(2 \times 10^{-3}\right)$ | 0.84 | $\left(2 \times 10^{-3}\right)$ | 0.110 | $\left(1 \times 10^{-3}\right)$ | 1.98 | $\left(1 \times 10^{-2}\right)$ | 0.62 | $\left(3 \times 10^{-3}\right)$ |
| RUV-inv (Ectl) | 0.90 | $\left(2 \times 10^{-3}\right)$ | 0.05 | $\left(8 \times 10^{-4}\right)$ | 0.87 | $\left(2 \times 10^{-3}\right)$ | 0.090 | $\left(6 \times 10^{-4}\right)$ | 1.14 | $\left(5 \times 10^{-4}\right)$ | 0.35 | $\left(4 \times 10^{-4}\right)$ |
| RUV-rinv (Ectl) | 0.89 | $\left(2 \times 10^{-3}\right)$ | 0.06 | $\left(1 \times 10^{-3}\right)$ | 0.87 | $\left(2 \times 10^{-3}\right)$ | 0.092 | $\left(7 \times 10^{-4}\right)$ | 1.35 | $\left(1 \times 10^{-3}\right)$ | 0.39 | $\left(5 \times 10^{-4}\right)$ |
| RUV-inv-rsvar (Ectl) | 0.90 | $\left(2 \times 10^{-3}\right)$ | 0.05 | $\left(2 \times 10^{-3}\right)$ | 0.87 | $\left(2 \times 10^{-3}\right)$ |  |  |  |  |  |  |
| RUV-rinv-rsvar (Ectl) | 0.89 | $\left(2 \times 10^{-3}\right)$ | 0.05 | $\left(2 \times 10^{-3}\right)$ | 0.86 | $\left(3 \times 10^{-3}\right)$ |  |  |  |  |  |  |
| RUV-inv-evar (Ectl) | 0.83 | $\left(4 \times 10^{-3}\right)$ | 0.01 | $\left(2 \times 10^{-4}\right)$ | 0.82 | $\left(2 \times 10^{-3}\right)$ |  |  |  |  |  |  |
| RUV-rinv-evar (Ectl) | 0.83 | $\left(3 \times 10^{-3}\right)$ | 0.01 | $\left(3 \times 10^{-4}\right)$ | 0.82 | $\left(2 \times 10^{-3}\right)$ |  |  |  |  |  |  |

Table 2 : $k=20$, moderately correlated, $n_{c}=60$, sparse.
First we discuss $\operatorname{RMSE}(\hat{\beta})$. All of the methods show a substantial improvement over "unadjusted," but the best performance comes from ICE and RUV-(r)inv with empirical controls. Without empirical controls, RUV-inv performs considerably worse. This is as expected, since $n_{c}=60$ is only a little larger than $m=50$, and $\hat{b}_{W X}$ suffers from over-fitting. Compared to RUV-inv without empirical controls, RUV-rinv without empirical controls performs much better - nearly as well as RUV-(r)inv with empirical controls. The ridging clearly helps. The remaining methods, all of which rely on an estimate of $k$, perform moderately well.

Next we discuss $\hat{\sigma}^{2}$. All of the methods show improvement over "unadjusted." The best overall performance comes from RUV-inv with empirical controls. RUV-rinv with empirical controls also performs quite well. RUV-4 performs exceptionally well in terms of $\operatorname{AVG}\left(\hat{\sigma}_{j}^{2} / \sigma_{j}^{2}\right)$, but less so in terms of $\operatorname{IQR}\left[\log \left(\hat{\sigma}_{j}^{2} / \sigma_{j}^{2}\right)\right]$; RUV-4 gets the overall "scale" of $\sigma^{2}$ right, but does not do as good of a job at estimating the individual $\sigma_{j}^{2}$. Both RUV-inv and RUV-rinv without empirical controls suffer from the fact that $n_{c}$ is only 60 , but in different ways. RUV-rinv performs worse than RUV-inv in terms of $\operatorname{AVG}\left(\hat{\sigma}_{j}^{2} / \sigma_{j}^{2}\right)$ but better in terms of $\operatorname{IQR}\left[\log \left(\hat{\sigma}_{j}^{2} / \sigma_{j}^{2}\right)\right]$. The remaining methods, which rely on an estimate of $k$, do not perform as well as the inverse method and its variants.

Now we discuss the discriminative power. Given our discussions of $\operatorname{RMSE}(\hat{\beta})$ and $\hat{\sigma}^{2}$, our findings regarding discriminative power are no surprise. All of the methods offer an improvement over "unadjusted." RUV-4 performs moderately well. RUV-inv suffers from the fact that $n_{c}$ is small and performs worse than RUV-4. RUV-rinv overcomes the problem of a small $n_{c}$ and outperforms both RUV-4 and RUV-inv. However, RUV-(r)inv with empirical controls performs the best. Empirical controls are the best way to handle the small $n_{c}$. Finally, note that out of SVA, LEAPP, and ICE, ICE performs the best.

There is considerable variation between the methods in terms of their control of the type 1 error rate. SVA, LEAPP, and RUV-4 are all notably anti-conservative. ICE is excessively conservative. RUV-inv is also
too conservative. RUV-rinv, and both RUV-inv and RUV-rinv with empirical controls, demonstrate quite good control of the type 1 error rate. Using rescaled variances in this case works, but is not needed. On the other hand, using empirical variances actually makes things worse. The problem is that even though only 500 of the 10,000 elements of $\beta$ are non-zero, this is still not sparse enough for the method of empirical variances. As a result, both the type 1 error rate and the discriminative power are adversely affected.

### 4.3.3 Results of the Remaining Simulations

We turn now to the other simulations. We begin with a comparison of RUV-4, RUV-inv, and RUV-rinv. The relative performance of these methods depends on whether $n_{c}=1000$ or $n_{c}=60$. When $n_{c}=1000$, RUV-inv performs best. When $n_{c}=60$, RUV-rinv performs best.

When $n_{c}=1000$, all three methods generally perform well in terms of discriminative power. RUV-inv performs the best. RUV-rinv is a close second. RUV-4 performs a little worse, particularly when $X$ is highly correlated with $W$. The differences between the methods are more pronounced in terms of the type 1 error rate. In terms of the type 1 error rate, RUV-inv clearly performs the best. RUV-inv exhibits good control of the type 1 error rate in most cases, but is notably anti-conservative when $k=70$ and $X$ is highly correlated with $W$. RUV-rinv is more anti-conservative than RUV-inv in all cases, and RUV-4 is even more anti-conservative than RUV-rinv. The differences between RUV-inv, RUV-rinv, and RUV-4 are most pronounced when $k=70$ or when $X$ is highly correlated with $W$.

When $n_{c}=60$, the story is much different. RUV-rinv performs the best by far, and RUV-inv performs the worst. RUV-inv is overly conservative and exhibits poor discriminative power. RUV-rinv is anti-conservative, but exhibits far more discriminative power. RUV-4 is more anti-conservative than RUV-rinv. The discriminative power of RUV-4 is generally somewhere between that of RUV-inv and RUV-rinv.

We now consider the use of empirical controls. The empirical controls work as expected. Performance of RUV-(r)inv with empirical controls is roughly the same as the performance of RUV-(r)inv without empirical controls but with $n_{c}=1000$. RUV-inv does slightly better than RUV-rinv. Importantly, note that the performance of the empirical controls is essentially the same whether the initial $n_{c}$ is equal to 1000 or 60 . In other words, if we begin with just 60 control genes, use RUV-rinv to generate empirical controls, and then apply RUV-(r)inv, we get results just as good as if we had 1000 control genes to begin with.

Next we consider the use of rescaled and empirical variances. The rescaled variances work as expected. The use of rescaled variances does not affect discriminative power in any way. The type 1 error rate is much better with rescaled variances than without. Across all 24 simulations, the average type 1 error rate with rescaled variances is never less than 0.04 nor greater than 0.08 . Without rescaled variances, the range is 0.05 to 0.24 . The empirical variances also work as expected. In all 8 "very sparse" simulations, the average type 1 error rate with empirical variances is 0.05 . The discriminative power with empirical variances is equal to or slightly better than the discriminative power without empirical variances. However, the usefulness of the empirical variances is limited to the case that $\beta$ is very sparse. In the 16 other simulations ("sparse" and "not sparse") the use of empirical controls leads to a serious decrease in performance.

Finally, we consider the performance of SVA, LEAPP, and ICE. Of these methods, ICE performs the best in all cases except those in which $k=70$ and $\beta$ is not sparse. Note that ICE tends to be extremely conservative, while SVA and LEAPP tend to be extremely anti-conservative. Finally, note that RUV-inv with empirical controls and rescaled variances performs at least well as any other method. When $\beta$ is very sparse, ICE performs as well as RUV-inv with empirical controls and rescaled variances, but only in terms of discriminative power (not type 1 error rate). SVA and LEAPP also perform reasonably well when $\beta$ is very sparse.

## 5 Data Results

In this section we apply the RUV methods to the datasets of Section 2. We analyze all 11 datasets the same way. In Section 5.1 we describe the details of the analyses. In Sections 5.2 and 5.3 we describe two types of plots we use to visualize the results of our analyses. In Section 5.4 we discuss the results of our analyses.

### 5.1 Analysis Details

Let $\kappa, \kappa_{1}$, and $\kappa_{2}$ be index variables that range over the symbols $\{0,1,2, \ldots, m-2, \mathrm{k}, \mathrm{i}, \mathrm{r}\}$. Note that $m$, in italics, is a variable that stands for the number of arrays; $k$, $i$, and $r$ are not variables, but just letters. Define estimates $\hat{\beta}^{(\kappa)}$ as follows: when $\kappa=0, \hat{\beta}^{(\kappa)}$ is the OLS estimate of $\beta$ in a regression of $Y$ on $X$; when $\kappa \in\{1, \ldots, m-2\}, \hat{\beta}^{(\kappa)}$ is the RUV-4 estimate of $\beta$ with $K=\kappa$; when $\kappa=\mathrm{k}, \hat{\beta}^{(\kappa)}$ is the RUV-4 estimate of $\beta$ with $K=\hat{k}$; when $\kappa=\mathrm{i}, \hat{\beta}^{(\kappa)}$ is the RUV-inv estimate of $\beta$; when $\kappa=\mathrm{r}, \hat{\beta}^{(\kappa)}$ is the RUV-rinv estimate of $\beta$. Define $\left(\hat{\sigma}^{2}\right)^{(\kappa)}, \hat{W}^{(\kappa)}, \hat{b}_{W X}^{(\kappa)}$, etc. similarly; note that $\hat{W}^{(\kappa)}$ and $\hat{b}_{W X}^{(\kappa)}$ are undefined when $\kappa=0$.

Let $v_{j}^{\left(\mathrm{s}, \kappa_{1}, \kappa_{2}\right)}$ denote the "standard" estimate of the variance of $\hat{\beta}_{j}^{\left(\kappa_{1}\right)}$, given an estimate $\left(\hat{\sigma}_{j}^{2}\right)^{\left(\kappa_{2}\right)}$ of $\sigma_{j}^{2}$. For example,

$$
\begin{equation*}
v_{j}^{(\mathrm{s}, 2, r)}=\left(\hat{\sigma}_{j}^{2}\right)^{(\mathrm{r})}\left[1+\left(\hat{b}_{W X}^{(2)}\right)^{\prime} \hat{b}_{W X}^{(2)}\right] \tag{242}
\end{equation*}
$$

and

$$
\begin{equation*}
v_{j}^{(\mathrm{s}, i, 4)}=\left(\hat{\sigma}_{j}^{2}\right)^{(4)}\left[1+\left(\hat{b}_{W X}^{(\mathrm{i})}\right)^{\prime} \hat{b}_{W X}^{(\mathrm{i})}\right] \tag{243}
\end{equation*}
$$

Let $v_{j}^{\left(\mathrm{e}, \kappa_{1}, \kappa_{2}\right)}$ denote the empirical estimate of the variance of $\hat{\beta}_{j}^{\left(\kappa_{1}\right)}$, given estimates $\left(\hat{\sigma}_{j}^{2}\right)^{\left(\kappa_{2}\right)}$ of $\sigma_{j}^{2}$.
Define the $t$ statistic

$$
\begin{equation*}
t_{j}^{\left(\mathrm{s}, \kappa_{1}, \kappa_{2}\right)} \equiv \frac{\hat{\beta}_{j}^{\left(\kappa_{1}\right)}}{\sqrt{v_{j}^{\left(\mathrm{s}, \kappa_{1}, \kappa_{2}\right)}}} \tag{244}
\end{equation*}
$$

and define $t_{j}^{\left(\mathrm{e}, \kappa_{1}, \kappa_{2}\right)}$ similarly. Define the $p$-value

$$
\begin{equation*}
p_{j}^{\left(\mathrm{s}, \kappa_{1}, \kappa_{2}\right)} \equiv \mathbb{P}\left[|t|>\left|t_{j}^{\left(\mathrm{s}, \kappa_{1}, \kappa_{2}\right)}\right| \mid t_{j}^{\left(\mathrm{s}, \kappa_{1}, \kappa_{2}\right)}\right] \tag{245}
\end{equation*}
$$

where $t$ follows a $t$ distribution with an appropriate number of degrees of freedom (e.g. $m-1$ degrees of freedom if $\kappa_{2}=0, m-6$ degrees of freedom if $\kappa_{2}=5$, or $\hat{r}$ degrees of freedom if $\kappa_{2}=\mathrm{i}$ ). Define $p_{j}^{\left(e, \kappa_{1}, \kappa_{2}\right)}$ similarly.

For fixed values of $\kappa_{1}$ and $\kappa_{2}$, consider the $N \leq n$ genes with the $N$ smallest $p$-values $p_{j}^{\left(\mathrm{s}, \kappa_{1}, \kappa_{2}\right)}$. Let $C^{\left(\mathrm{s}, \kappa_{1}, \kappa_{2}, N\right)}$ denote the number of these top-ranked genes that are located on the X or Y chromosomes (we choose " $C$ " for "top rank Count"). $C^{\left(\mathrm{s}, \kappa_{1}, \kappa_{2}, N\right)}$ is one of the most important statistics we use to compare the effectiveness of the various methods. Next define the statistic

$$
\begin{equation*}
T^{\left(\mathrm{s}, \kappa_{1}, \kappa_{2}\right)} \equiv \log \left(\frac{\operatorname{median}_{j}\left|t_{j}^{\left(\mathrm{s}, \kappa_{1}, \kappa_{2}\right)}\right|}{T_{0}}\right) \tag{246}
\end{equation*}
$$

Here $T_{0}$ is the $50^{\text {th }}$ percentile of $|t|$, where $t$ follows a $t$ distribution with an appropriate number of degrees of freedom. Assuming $\beta$ is sparse, $T^{\left(\mathrm{s}, \kappa_{1}, \kappa_{2}\right)}$ is a good measure of whether the $t$-statistics $t_{j}^{\left(\mathrm{s}, \kappa_{1}, \kappa_{2}\right)}$ are too big or too small. Now, consider all genes that do not come from the X or Y chromosomes. Let $E^{\left(\mathrm{s}, \kappa_{1}, \kappa_{2}\right)}$ denote the fraction of these genes whose $p$-value $p_{j}^{\left(\mathrm{s}, \kappa_{1}, \kappa_{2}\right)}$ is less than 0.05 . We use $E^{\left(\mathrm{s}, \kappa_{1}, \kappa_{2}\right)}$ as an effective type 1 error rate. ${ }^{4}$ Finally, define $C^{\left(\mathrm{e}, \kappa_{1}, \kappa_{2}, N\right)}, T^{\left(\mathrm{e}, \kappa_{1}, \kappa_{2}\right)}$, and $E^{\left(\mathrm{e}, \kappa_{1}, \kappa_{2}\right)}$ similarly to $C^{\left(\mathrm{s}, \kappa_{1}, \kappa_{2}, N\right)}, T^{\left(\mathrm{s}, \kappa_{1}, \kappa_{2}\right)}$, and $E^{\left(\mathrm{s}, \kappa_{1}, \kappa_{2}\right)}$.

[^4]Our analyses proceed as follows. First we define three sets of control genes. The first set is the set of housekeeping genes. The second set includes all genes. The third set is a set of empirical controls. Then, for each set of control genes, for each possible pair ( $\kappa_{1}, \kappa_{2}$ ), and for each value of $N$ in $\{20,40,60,80,100\}$, we calculate $C^{\left(\mathrm{s}, \kappa_{1}, \kappa_{2}, N\right)}, T^{\left(\mathrm{s}, \kappa_{1}, \kappa_{2}\right)}, C^{\left(\mathrm{e}, \kappa_{1}, \kappa_{2}, N\right)}$, and $T^{\left(\mathrm{e}, \kappa_{1}, \kappa_{2}\right)}$. We also calculate $E^{(\mathrm{s}, \kappa, \kappa)}$ and $E^{(\mathrm{e}, \kappa, \kappa)}$ for $\kappa \in\{k, i, r\}$.

Some notes: All of our models include a $Z=1_{m \times 1}$ term. This is not reflected in the notation above. All of our estimates of $\sigma^{2}$ are unadjusted; we do not use Limma. To generate the empirical controls, we simply regress $Y$ on $X$, compute FDR-adjusted $p$-values, and designate all genes with FDR-adjusted $p$-values greater than 0.5 as empirical controls. This is a very crude application of the strategy of empirical controls. The rationale for this choice of empirical controls is to demonstrate that even a crude application of the strategy will often be effective. Still, we encourage researchers to be cautious in their own applications of the strategy.

In addition to the analysis just described, we also analyze each dataset by SVA, LEAPP, and ICE. For each of these methods, we rank genes by $p$-value, and count the number of genes in the top $20 / 40 / 60 /$ 80 / 100 that are on the X or Y chromosomes. We also calculate an "effective type 1 error rate" analogous to the one described above.

### 5.2 Summary Plots

We need a way to visualize our results. We accomplish this with "summary plots." An example summary plot is given in Figure 11. Summary plots are rather complex. The purpose of this section is to describe them.

Ignoring the color scales on the far left, each summary plot can be divided into 4 identically "shaped" divisions. On the top are two divisions with colors ranging from black to red to green to blue. On the bottom are two divisions with colors ranging from red to white to blue. Each division can be further divided into nine subdivisions. These subdivisions do not all have the same shape. The top left subdivision is a single colored square; the middle subdivision is a giant multi-colored square with many rows and columns; etc.

We now describe the top left division. The top left division is a plot of $C^{\left(s, \kappa_{1}, \kappa_{2}, N\right)}$ for all values of $\left(\kappa_{1}, \kappa_{2}\right)$. Each row of the plot represents a different value of $\kappa_{1}$; each column of the plot represents a different value of $\kappa_{2}$. The value of $C^{\left(\mathrm{s}, \kappa_{1}, \kappa_{2}, N\right)}$ is given by the color. An example: The top left corner of the bottom right subdivision is a light greenish yellow color. Referring to the color scale on the far left, we see that this color corresponds to a value of 24 . Thus $C^{(\mathrm{s}, \mathrm{k}, \mathrm{k}, 40)}=24$. In other words, if we run RUV-4 with $K=\hat{k}$ and rank genes by $p$-value, we will find that 24 of the top 40 genes are on the X or Y chromosomes. A second example: In the middle column of the middle-right subdivision, the $11^{\text {th }}$ square from the top is a light green color. Referring to the color scale on the far left, we see that this color corresponds to a value of 25 . Thus $C^{(\mathrm{s}, 11, \mathrm{i}, 40)}=25$. In other words, if we run RUV-4 with $K=11$ to get our estimate of $\beta$, but estimate $\sigma^{2}$ using RUV-inv, we will find that 25 of the resulting top 40 genes are on the X or Y chromosomes. Note the black lines in the $16^{\text {th }}$ row and $16^{\text {th }}$ column of the middle subdivision. These black lines represent $\hat{k} ; \hat{k}$ in this example is equal to 16 . Note that the color at the intersection of these lines is the same as the color in the top left square of the bottom right subdivision.

The other divisions are analogous to the top left division. The top right division is a plot of $C^{\left(e, \kappa_{1}, \kappa_{2}, N\right)}$ instead of $C^{\left(\mathrm{s}, \kappa_{1}, \kappa_{2}, N\right)}$. The bottom left division is a plot of $T^{\left(\mathrm{s}, \kappa_{1}, \kappa_{2}\right)}$. The bottom right division is a plot of $T^{\left(e, \kappa_{1}, \kappa_{2}\right)}$. Note that in the case of the bottom divisions, shades of red correspond to $t$-values that are generally "too small." $p$-vales are therefore "too big" and the method is conservative. Conversely, shades of blue correspond to $t$-values that are generally "too big," $p$-vales that are "too small," and the method is anti-conservative. White is just right.

We have described the mechanics of reading the summary plots. We now give a few brief examples of how the summary plots can be used to learn something. First note that the upper right division is "greener" than the upper left division. From this we learn that using empirical variances increases the discriminative power (on this dataset). Next observe that the lower right division is "whiter" than the lower left division. From this we learn that using empirical variances leads to better control of the type 1 error rate. Now consider just the middle subdivision of the upper left division. Note that as we move downwards through the rows,

Figure 11: Example Summary Plots. Alzheimer's (Preprocessed) dataset, HK controls. X/Y gene counts are out of the top 40 genes.
the rows are roughly non-decreasing in green-ness. This tells us that the quality of $\hat{\beta}$ as an estimator of $\beta$ is roughly non-decreasing in $K$. Conversely, moving from left to right, the columns first get greener, and then fall to black. This tells us that $\hat{\sigma}^{2}$ is only a good estimator of $\sigma^{2}$ when $K$ is somewhere between 6 and 17 .

### 5.3 Projection Plots

In Sections 3.4 and 3.8 we considered examples in which $m=2$. We were able to plot each gene as a point in 2 -dimensional space. These plots were very helpful for visualizing and understanding RUV-4. We would like to produce similar plots for $m>2$. Such plots would be a very useful diagnostic tool when applying RUV-4 to real data.

When $m=2$ and $K=1$ the column space of $\hat{W}$ can be represented as a line passing through the origin.

The slope of the line is $\hat{b}_{W X}$. When $m>2$ and $K>1$ this is no longer possible. The column space of $\hat{W}$ is a hyperplane and cannot be graphed in two dimensions. Still, it is possible to produce similar, helpful plots.

One possibility is to produce one plot for each factor. Recall that in the figures of Section 3.4, the vertical axis represents $b_{Y X}=X^{\prime} Y$ and the horizontal axis represents $\hat{\alpha}$. When $m>2, K$ will generally be greater than 1 and $\hat{\alpha}$ will have more than one row. So, we might want to make a collection of $K$ plots, one for each row of $\hat{\alpha}$. More specifically, for each $i, 1 \leq i \leq K$, we could plot $b_{Y X}$ vs. $\hat{\alpha}_{i \star}$. Examples of such plots can be found in Figure 12, A and B. Here, $i=1,4$. In these plots the vertical position of the $j^{\text {th }}$ dot represents $X^{\prime} Y_{\star j}$ and the horizontal position of the dot represents $\hat{\alpha}_{i j}=\left(\hat{W}_{0}\right)_{\star i}^{\prime} Y_{\star j}$. In other words, each dot represents a projection of $Y_{\star j}$ into the 2-dimensional subspace spanned by $X$ and the $i^{\text {th }}$ column of $\hat{W}_{0}$. We therefore refer to these plots as projection plots. The black line is a cross section of the hyperplane spanned by $\hat{W}$. This line passes through the origin and its slope is the $i^{\text {th }}$ entry of $\hat{b}_{W X}$.

Projection plots allow us to see visually how the observed signal of the factor of interest (i.e., $b_{Y X}$ ) varies with the observed signal of the $i^{\text {th }}$ unwanted factor (i.e., $\hat{\alpha}_{i \star}$ ). These projection plots are useful diagnostic tools. For example, we may use them to see whether the "practical assumptions" of Section 3.8.3 seem plausible. We may use the projection plots to visually inspect whether the negative controls seem to be well described by a linear function function that passes through the origin. We may use the projection plots to visually inspect whether the negative controls seem "representative." More generally, we can use projection plots to learn interesting features of the data, such as outliers, that may not be immediately apparent otherwise.

One problem with these plots is that, unlike in Section 3.4, the vertical distance from a dot to the black line does not represent $\hat{\beta}_{j}$. If it were possible to construct a $(K+1)$-dimensional graph in which the "vertical" axis represented $b_{Y X}$ and the $K$ "horizontal" axes represented the $K$ rows of $\hat{\alpha}$, and we drew a hyperplane that spanned the space of $\hat{W}$, then $\hat{\beta}_{j}$ would be represented by the vertical distance from the $j^{\text {th }}$ dot to the hyperplane. But of course the height of the hyperplane may vary along each of the $K$ horizontal axes, and this is not something that we are able to capture in our projection plots. Instead, our black line is only a single cross-section of the hyperplane.

One way to deal with this issue is to "adjust" for the other factors. Instead of plotting $b_{Y X}$ on the vertical axis, we may plot an "adjusted" $b_{Y X}$. More specifically, suppose we are creating a plot for factor $i$, and as before we plot $\hat{\alpha}_{i \star}$ on the horizontal axis. Instead of plotting $b_{Y X}$ on the vertical axis we may wish to plot $b_{Y X}-\hat{b}_{W X}^{(-i)} \hat{\alpha}^{(-i)}$, where $\hat{b}_{W X}^{(-i)}$ is $\hat{b}_{W X}$ with the $i^{\text {th }}$ entry removed and $\hat{\alpha}^{(-i)}$ is $\hat{\alpha}$ with the $i^{\text {th }}$ row removed. (It may be helpful at this point to recall equation (37). It may also be helpful to note that the quantity to which we refer could also be written as $\hat{b}_{Y X . W^{(-i)}}$.) Examples of such plots are given in Figure 12, C and D. We still draw a black line that passes through the origin and whose slope is the $i^{\text {th }}$ entry of $\hat{b}_{W X}$. In these plots, it is indeed the case that $\hat{\beta}_{j}$ is the vertical distance from the $j^{\text {th }}$ dot to the black line. Unfortunately, however, these plots lose their interpretation as "projection plots." The points are no longer (orthogonal) projections into the space spanned by $X$ and the $i^{\text {th }}$ column of $\hat{W}_{0}$. Despite this, we will refer to these plots somewhat inappropriately as "adjusted projection plots."

As with the unadjusted projection plots, what the adjusted projection plots show us is how the observed signal of the factor of interest varies with the observed signal of the $i^{\text {th }}$ unwanted factor - but after adjustment for the other $K-1$ unwanted factors. This adjustment allows us to see more clearly the joint variation between the observed signal of the factor of interest and the observed signal of the $i^{\text {th }}$ unwanted factor. In Figure 12, compare C to A and D to B. The dots in C and D are more tightly clustered around the black line than the dots in A and B. For the green dots this is simple mathematical fact; the hyperplane, after all, is fit to the negative controls. Increasing $K$ will result in an even tighter fit. For the other dots, however, the tighter fit is an indication that the adjustment is effectively removing unwanted variation. Note that adjusted projection plots, because they give some sense of the quality of the adjustment, are a useful tool in choosing an appropriate $K$.

We now consider a final variant of projection plot. Recall that for a (unadjusted) projection plot, we project $Y$ into the 2-dimensional subspace spanned by $X$ and the $i^{\text {th }}$ column of $\hat{W}_{0}$. More formally, we may
define the projection operator

$$
\begin{equation*}
\tilde{P}^{(i)} \equiv\left(\left(\hat{W}_{0}\right)_{\star i} \mid X\right)^{\prime} \tag{247}
\end{equation*}
$$

A projection plot of factor $i$ is simply a plot of

$$
\begin{equation*}
\tilde{Y}^{(i)} \equiv \tilde{P}^{(i)} Y \tag{248}
\end{equation*}
$$

$\tilde{Y}^{(i)}$ is a $2 \times n$ matrix. Each column of $\tilde{Y}^{(i)}$ corresponds to one point on the projection plot; the entry in the first row gives the horizontal component, and the entry in the second row gives the vertical component.

Note in particular that these projection plots are defined in terms of the individual columns of $\hat{W}_{0}$. There is one projection plot for the first column of $\hat{W}_{0}$, another projection plot for the second column of $\hat{W}_{0}$, etc. However, we need not restrict ourselves to individual columns. We may also wish to consider projection plots that are defined in terms of linear combinations of the columns of $\hat{W}_{0}$. More formally, let $q$ be some arbitrary $K \times 1$ vector of unit length. We may wish to consider projections of the form

$$
\begin{equation*}
\tilde{P}^{(q)} \equiv\left(\hat{W}_{0} q \mid X\right)^{\prime} \tag{249}
\end{equation*}
$$

Each choice of $q$ gives us a different perspective of the data. Is there some value of $q$ that is particularly illuminating? Indeed there is:

$$
\frac{\hat{b}_{W X}^{\prime}}{\left\|\hat{b}_{W X}^{\prime}\right\|}
$$

This is the gradient direction of the hyperplane. We define $\tilde{P}$ (without a superscript) as

$$
\begin{equation*}
\tilde{P} \equiv\left(\left.\frac{\hat{W}_{0} \hat{b}_{W X}^{\prime}}{\left\|\hat{b}_{W X}^{\prime}\right\|} \right\rvert\, X\right)^{\prime} \tag{250}
\end{equation*}
$$

and let $\tilde{Y} \equiv \tilde{P} Y$. We refer to

$$
\frac{\hat{W}_{0} \hat{b}_{W X}^{\prime}}{\left\|\hat{b}_{W X}^{\prime}\right\|}
$$

as the "gradient factor" and to a plot of $\tilde{Y}$ as a "gradient factor projection plot." For an example, see Figure 12, E. As before the black line is a cross section of the hyperplane. This line passes through the origin and has slope $\left\|\hat{b}_{W X}^{\prime}\right\|$.

The gradient factor projection plot combines the two main advantages of unadjusted and adjusted projection plots: it is a true projection plot and the vertical distance of the $j^{\text {th }}$ dot to the black line is equal to $\hat{\beta}_{j}$. Indeed, the 2-dimensional subspace spanned by $X$ and the gradient factor is a uniquely special subspace. The value of $\hat{\beta}_{j}$ is determined entirely by the projection of $Y_{\star j}$ into this subspace, i.e. by $\tilde{Y}_{\star j}$. Components of $Y_{\star j}$ orthogonal to both $X$ and the gradient factor play no role in the determination of $\hat{\beta}_{j}$. Observe:

$$
\begin{align*}
\hat{\beta} & =b_{Y X}-\hat{b}_{W X} \hat{\alpha}  \tag{251}\\
& =X^{\prime} Y-\hat{b}_{W X} \hat{W}_{0}^{\prime} Y  \tag{252}\\
& =\tilde{Y}_{2 \star}-\left\|\hat{b}_{W X}^{\prime}\right\| \tilde{Y}_{1 \star} . \tag{253}
\end{align*}
$$

So $\hat{\beta}_{j}$ is determined by $\tilde{Y}_{2, j}$ and $\tilde{Y}_{1, j}$. Components of $Y_{\star j}$ orthogonal to both $X$ and the gradient factor do not matter. More specifically, we see that $\hat{\beta}_{j}$ is given by the vertical distance from the $j^{\text {th }}$ dot to the line. Note that $\tilde{Y}_{2, j}$ is the height of the $j^{\text {th }}$ dot and $\left\|\hat{b}_{W X}^{\prime}\right\| \tilde{Y}_{1, j}$ is the height of the line directly below the $j^{\text {th }}$ dot.

Gradient factor projection plots can be easily generalized to RUV-2. Although $\hat{W}_{0}$ does not play the same central role in RUV-2 that it does in RUV-4, RUV-2 still produces an estimate of $W$, and the columnspace of $\hat{W}$ defines a hyperplane. This hyperplane has a gradient, and we can produce a gradient factor projection plot. For an example, see Figure 12, F.

The gradient factor projection plot is arguably the single most useful projection plot. The other projection plots are also very helpful and we encourage their use, but it can be overwhelming to present all of them (for the various values of $i$ ) in a research paper. In what follows we therefore limit ourselves to gradient factor projection plots, and refer to these plots simply as "projection plots."

Figure 12: Projection Plots for the Gender dataset. HK controls. See text for details. Coloring scheme: negative controls, green; X-genes, pink; Y-genes, blue; X/Y-genes, purple; all other genes, gray. Note that we plot the gray dots first, followed by the green, the pink, the blue, and the purple. Thus many of the green and gray points are hidden behind the pink.

### 5.4 Results

We now discuss the results of our analyses. A complete set of summary plots is provided in Section C of the SM. Section C also provides projection plots for RUV-2, RUV-4, RUV-inv, and RUV-rinv. Section D provides a complete set of tables listing the values of top-ranked gender gene counts and effective type 1 error rates for Combat(where applicable), SVA, LEAPP, ICE, RUV-4, RUV-inv, RUV-rinv.

### 5.4.1 The Practical Assumptions

We begin our discussion by inspecting the projection plots. In Section 3.8 we noted that the success of RUV-4 depends critically on two "practical assumptions." The first is that the ( $\left.\hat{\alpha}_{\star j}, B_{j}(\alpha)\right)$ pairs are well described by a linear function passing through the origin. The second is that the control genes are "representative" of the other genes. We would like to check that these assumptions are plausible.

Now, $B(\alpha)$ is unobservable. However, in our model, $b_{Y X}=\beta+B(\alpha)+\zeta$. Thus, if $\beta_{j}=0$ it follows that $\left(b_{Y X}\right)_{j} \approx B_{j}(\alpha)$. Moreover, we do not expect gender to affect the expression levels of more than a handful of genes, and we therefore expect that $\beta_{j}=0$ for the vast majority of the genes; we believe that $\beta$ is very sparse. Thus, if it is true that the ( $\hat{\alpha}_{\star j}, B_{j}(\alpha)$ ) pairs are well described by a linear function passing through the origin, it should also be the case that the vast majority of the $\left(\hat{\alpha}_{\star j},\left(b_{Y X}\right)_{j}\right)$ pairs are well described by a linear function passing through the origin. An examination of the projection plots suggests that this is indeed the case. See, for example, Figures 12 and 13.

An examination of the projection plots also suggests that the control genes are "representative" of the rest of the genes. See, for example, Figure 12. The green dots are more or less representative of the gray dots. The housekeeping genes in the TCGA datasets appear to be an exception. See, for example, the top left plot of Figure 13. However, the problem evident in Figure 13 is less an issue of the housekeeping genes being "unrepresentative" than it is an issue of RUV-inv overfitting to the housekeeping genes. The problem goes away when we use RUV-rinv instead.

### 5.4.2 RUV-2 vs RUV-4

We very briefly compare the performance of RUV-2 to that of RUV-4. Our analysis of RUV-2 is limited to projection plots. In many cases RUV-2 appears to perform fairly well. See, for example the RUV-2 projection plots of the TCGA datasets with housekeeping or empirical controls (Section C of the SM). In many other cases, however, RUV-2 suffers from the problems outlined in Section 3.4. See, for example, Figure 12; RUV-4 is clearly preferable.

Many of the examples in Section C of the SM are far more dramatic than Figure 12. This is particularly true when the control genes are misspecified. In the case of the Alzheimer's and Gender datasets, RUV-4 performs just fine even when all genes are used as control genes. RUV-2, however, performs horribly. In the case of the TCGA data, both RUV-2 and RUV-4 are adversely affected by misspecification of the control genes. However, RUV-2 performs far worse.

Finally, note that the comparison here between RUV-2 and RUV-4 is not entirely fair. RUV-2 is more sensitive to the choice of $K$ than RUV-4. In their discussion of RUV-2, Gagnon-Bartsch and Speed (2012) emphasize the importance of exercising judgment when selecting $K$, and using quality measures such as RLE plots, $p$-value histograms, and gene rankings to guide the choice of $K$. We did not do that here. Had we been more careful in our selection of $K$, the performance of RUV-2 may have been considerably better.

### 5.4.3 Choice of $K$

We now examine the choice of $K$ on the performance of RUV-4. Our first observation is that, in many cases, setting $K$ to be very large does not notably hurt the performance of $\hat{\beta}$. See, for example, Figure 11. However, there are exceptions. One exception is when $K$ is large relative to $n_{c}$. This occurs in the TCGA examples when we use housekeeping genes as controls. See Figures 31, 32, and 33 in the SM. The summary plots show that the quality of $\hat{\beta}$ decreases for large $K$; the projection plots (RUV-inv) show that the reason is overfitting to the control genes. A second exception is when the control genes are misspecified.

Figure 13: Projection Plots of TCGA HG-U133A.

Misspecification of the control genes is not necessarily a problem in and of itself, but becomes a problem when $K$ is very large. This can be seen in the TCGA examples. When we use all genes as control genes, the quality of $\hat{\beta}$ is poor when $K$ is greater than 100 or so. See Figures 31,32 , and 33 in the SM. The summary plots show that the quality of $\hat{\beta}$ decreases for large $K$; the projection plots (RUV-4 and especially RUV-inv) show that the reason is misspecification of the control genes.

Our second observation is that $\hat{\sigma}^{2}$ performs poorly both when $K$ is too small and when $K$ is too large. See, for example, Figure 11. The discriminative power is poor both when $K$ is small and when $K$ is large. Moreover, the plot of $T^{\left(\mathrm{s}, \kappa_{1}, \kappa_{2}\right)}$ suggests that $\hat{\sigma}^{2}$ is generally too large when $K$ is small and $\hat{\sigma}^{2}$ is too small
when $K$ is large. However, there is good news as well. In many cases, the discriminative power is only hurt by a poor estimate of $\hat{\sigma}^{2}$ when the value of $K$ is relatively extreme. See, for example, Figures 31, 32, and 33 in the SM. As long as $K$ is not so small that $\hat{\sigma}^{2}$ is severely biased by unwanted variation that has not been properly adjusted for, and as long as $K$ is not so large that $\hat{\sigma}^{2}$ must be estimated using only a few degrees of freedom, $\hat{\sigma}^{2}$ is "good enough" from the point of view of discriminative power. Of course, the overall scale of $\hat{\sigma}^{2}$ (i.e. $\dot{\sigma}^{2}$ ) remains an issue. The plots of $T^{\left(\mathrm{s}, \kappa_{1}, \kappa_{2}\right)}$ suggest that $\dot{\sigma}^{2}-$ and thus the type 1 error rate is fairly sensitive to the choice of $K$. Fortunately, we can solve this problem by using empirical variances.

Our final observation is that $\hat{k}$ is a decent, but not great, choice of $K$. Although $\hat{k}$ may be informative, we do not advise relying solely on $\hat{k}$ when selecting $K$ in practice. Gene rankings, $p$-value histograms, projection plots, etc. should be considered as well. Perhaps more importantly, we observe that in most of the examples, there is no single "best" choice for $K$. A value of $K$ that is good for $\hat{\beta}$ is not necessarily good for $\hat{\sigma}^{2}$, and vice versa. It may be better to select two values of $K$; one value, $K_{1}$, could be used when estimating $\beta$, and another, $K_{2}$, could be used when estimating $\hat{\sigma}^{2}$. Note, however, that even if we allow ourselves to use two separate $K$ s, it is still not necessarily the case that a choice of $\left(K_{1}, K_{2}\right)$ that provides good discriminative power will also provide a good type 1 error rate. The problem of selecting $K$ is indeed very difficult.

### 5.4.4 Choice of Control Genes

We now consider the choice of control genes. As we noted in the previous section, all three sets of control genes work fairly well when $m$ (and therefore $K$ ) is relatively small. When $K$ is fairly small, there is no problem of overfitting to the control genes, nor are there any problems due to misspecification of the control genes. Indeed, all three sets of control genes work fairly well for the Alzheimer's and Gender datasets.

The story is very different with the TCGA datasets. With housekeeping genes, $n_{c}$ is too small. This is not necessarily a problem for all methods. RUV-rinv continues to perform well. RUV-4 with $K=\hat{k}$ performs moderately well. RUV-inv, however, overfits to the control genes and performs horribly. Both $\hat{\beta}$ and $\hat{\sigma}^{2}$ are adversely affected. With all genes as control genes the situation is even worse. RUV-inv continues to perform horribly. RUV-4 and RUV-rinv now perform poorly as well. Unlike with the housekeeping genes, however, only $\hat{\beta}$ is adversely affected. See the summary plots for evidence. With the empirical controls, the situation is much better. With empirical controls, RUV-4, RUV-inv, and RUV-rinv all perform very well. Moreover, RUV-4 performs well for a very wide range of $K$. In the examples of this paper, empirical controls are an unequivocal success.

### 5.4.5 Use of Empirical Variances

We now consider the use of empirical variances. In the simulations of Section 4.3 we found that empirical variances are only effective when $\beta$ is very sparse. Fortunately, we believe that $\beta$ is in fact very sparse in the examples of this section. Indeed, we find empirical variances to be very helpful. Comparing plots of $T^{\left(\mathrm{s}, \kappa_{1}, \kappa_{2}\right)}$ to plots of $T^{\left(\mathrm{e}, \kappa_{1}, \kappa_{2}\right)}$ suggests that the use of empirical variances helps control the type 1 error rate. The tables in Section D in the SM confirm this directly.

The benefits of using empirical variances are not limited to better control of the type 1 error rate. In the case of the Alzheimer's dataset, the use of empirical variances also increases discriminative power. Presumably, the reason the use of empirical variances improves discriminative power in the Alzheimer's dataset is that $m$ is fairly small, and estimates of $\sigma^{2}$ are therefore somewhat noisy. The method of empirical variances shrinks estimates of the variances to the mean. In this sense, the method of empirical variances plays a role similar to the role more commonly played by Limma. Note that in the other datasets, the use of empirical variances neither notably increases nor notably decreases discriminative power. The use of empirical variances seems suitable for general use whenever $\beta$ is known to be very sparse.

### 5.4.6 A Comparison of Methods

We now compare the performance of Combat, SVA, LEAPP, ICE, and the variants of RUV. We begin with the variants of RUV. A quick glance at the summary plots of Section C in the SM confirms that RUV-inv
works largely as intended. By setting $K=m-1$ and estimating $\sigma^{2}$ with the inverse method we avoid the problem of estimating $k$ but get results nearly as good as if we had chosen an optimal value of $K$. The usual caveats apply - RUV-inv will fail if $m$ is large and $n_{c}$ is small or the control genes are misspecified. However, these issues can be overcome by using either RUV-rinv, empirical controls, or both. Indeed, somewhat closer inspection reveals that RUV-rinv is generally preferable to RUV-inv. There are several examples in which RUV-rinv clearly outperforms RUV-inv. However, there are no examples in which RUV-inv substantially outperforms RUV-rinv. Thus, when in doubt, we find it is generally advisable to use RUV-rinv. We also advise using empirical controls whenever $\beta$ is known to be sparse, and empirical variances whenever whenever $\beta$ is known to be very sparse.

We now consider the results of SVA, LEAPP, and ICE as well. In the simulations of Section 4.3 we found that all of these methods perform reasonably well when $\beta$ is sparse and $X$ is not strongly correlated with $W$. See Tables 4 and 16 in the SM. In our example datasets, $\beta$ is sparse and $X$ does not appear to be strongly correlated with $W$ (see, for example, the projection plots; the slopes are not steep). We therefore expect all of the methods to do reasonably well. Indeed they do. Table 3 provides a brief summary of results for SVA, LEAPP, ICE, RUV-4, RUV-inv, RUV-rinv. Results for Combat are also included for datasets with known batches - lab and platform in the case of the Gender dataset, and platform in the case of the TCGA Combined dataset. Section D in the SM provides a more complete set of results. As we see in Table 3, the performance of the RUV methods compares well with that of Combat, SVA, LEAPP, and ICE.

Particularly encouraging is the ability of these methods to effectively combine the TCGA datasets. Consider the TCGA Combined dataset. Without any adjustment, results are poor. Only 16 of the top 60 genes are on the X or Y chromosome. Now consider any of the three datasets that make up the TCGA Combined dataset (i.e. the three "subset" datasets). In each case, without any adjustment, 18 of the top 60 genes are on the X or Y chromosome. Thus, despite the fact we triple our sample size, combining these three datasets into one without performing any adjustment actually hurts performance. Now suppose we adjust. If we stick to a single "subset" dataset, we might find up to 23 genes out of the top 60 are on the X or Y chromosome. However, if we combine the three subset datasets to make the Combined dataset, we might find up to 27 genes out of the top 60 that are on the X or Y chromosome. Thus, when we adjust, it is no longer the case that combining datasets hurts us; it now helps us.

Finally, we draw attention to the special cases of the Alzheimer's and Gender datasets without preprocessing. Without preprocessing, these datasets are extremely noisy. Nonetheless, the RUV methods perform exceedingly well. Indeed, the results without preprocessing are about as good as the results with preprocessing. This may not be enormously helpful to the world of microarrays - microarray data is routinely preprocessed. Nonetheless, we find these results very encouraging. We feel these results suggest that the RUV methods are relatively robust. We are therefore hopeful that the basic RUV methodology will prove useful to many different types of high dimensional data.

## 6 Discussion

We now provide some final commentary. We begin by reconsidering the differences between RUV-2 and RUV-4. In Section 3.4 we discussed the differences between RUV-2 and RUV-4 extensively. For one, we found that RUV-4 is less sensitive than RUV-2 to the choice of $K$. For another, we found that RUV-4 is less sensitive to violations of the control gene assumption. This second observation, however, is only part of a larger point, which is that RUV-2 and RUV-4 use control genes differently. In some sense, both RUV-2 and RUV-4 use control genes as a reference point for a comparison. The variation present in the control genes is assumed to be unwanted variation. The negative control genes tell us what the unwanted variation "looks like." When we look at variation in non-control genes, the question we must answer is, "is this variation of interest?" To answer this question, we compare the variation we observe in the non-control genes to the variation we observe in the control genes. If the variation we observe in a non-control gene looks like the variation we observe in the negative controls, we conclude that there is no interesting variation present in that gene. However, if the variation in the non-control gene does not look like the variation present in the negative controls, we conclude that that there is indeed some interesting variation in that gene, i.e. that the gene is differentially expressed with respect to the factor of interest.

The difference between RUV-2 and RUV-4 is that the comparison between the non-control genes and the control genes is more "direct" with RUV-4 than it is with RUV-2. In Section 3.5.3, we found that the RUV-4 estimate of $\beta$ might outperform even the (hypothetical) OLS estimate of $\beta$ (if $W$ were somehow known). In the discussion of Section 3.5.4, we noted that this enhanced performance of RUV-4 relies on the assumption that the $\alpha_{\star j_{c}}$ are representative of the $\alpha_{\star j_{\bar{c}}}$. In our discussion of the functional approach, we took this a step further. The assumption that the control genes are representative takes on a central role. From the functional point of view, the role of control genes in RUV-4 is to provide an estimate of the background signal, against which the signal of the non-control genes may be compared. To determine whether a non-control gene $j_{\bar{c}}$ is differentially expressed, we first compute its observed signal $\left(b_{Y X}\right)_{j_{\bar{c}}}$. We then calculate $\hat{\alpha}_{\star j_{\bar{c}}}$ to see how this gene has been affected by the unwanted factors. Next we check to see how much signal we observe from control genes that have been similarly affected by the unwanted factors, i.e. have similar values of $\hat{\alpha}$. Finally, we compare the observed signal of gene $j_{\bar{c}}$ to the observed signal of the comparable control genes (those that have similar values of $\hat{\alpha}$ ). If the observed signal of gene $j_{\bar{c}}$ is about the same as that of the comparable control genes, we conclude that the observed signal of gene $j_{\bar{c}}$ is just due to unwanted variation and that gene $j_{\bar{c}}$ is not differentially expressed. If, however, the observed signal of gene $j_{\bar{c}}$ is substantially different from the observed signal of the comparable control genes, we conclude that gene $j_{\bar{c}}$ is differentially expressed.

With RUV-2, the comparison between the non-control genes and control genes is less direct. The comparison is more strongly intermediated by the linear model. With RUV-2 it is not necessary that the values of $\alpha$ for the control genes are in any way representative of the values of $\alpha$ for the non-control genes. All that matters is that the control genes are affected by the same unwanted factors as the non-control genes, and that the linear model holds. With RUV-2 we use the control genes simply to identify the linear subspace in which the unwanted variation resides (Recall the RUV-2 estimate of $W$ is better than the RUV-4 estimate of $W$, even if the RUV-4 estimate of $\beta$ is better than the RUV-2 estimate of $\beta$. Indeed, unlike the RUV-4 estimate of $W$, it can be shown that under suitable conditions the RUV-2 estimate of $W$ is consistent.). We then completely remove any and all variation within this subspace. Whether the patterns of variation within this subspace are similar between the control genes and the non-control genes is a moot point; all of the variation in this subspace is removed.

This difference between RUV-2 and RUV-4 has important practical implications. We have made a strong case in this paper for the use of RUV-4. However, RUV-4 is not necessarily preferable to RUV-2 in all circumstances. Consider a case in which only a small number of genes are differentially expressed with respect to the factor of interest $X$. Suppose that these genes are also strongly affected by an unknown, unwanted factor $W$. Suppose also, however, that the unwanted factor $W$ affects only a small number of the control genes. Then the values of $\alpha$ for the control genes will not be representative of the values of $\alpha$ for the genes that are differentially expressed. The values of $\alpha$ for the genes that are differentially expressed will be large (these genes are strongly affected by $W$ ) but the values of the $\alpha$ for the control genes will be mostly 0
(most control genes are unaffected by $W$ ).
As a concrete example, suppose there is a genetic disease and it is known that the disease is somehow caused by a gene or genes on the X chromosome. A researcher wants to perform a differential expression analysis to find the gene(s) associated with the disease. Suppose that both men and women are in the study. Gender will be an important source of unwanted biological variation. Suppose, however, that information on the gender of the people in the study is missing. The researcher therefore decides to use genes from the Y chromosome as negative controls. Since the researcher would also like to get a good estimate of any unwanted technical factors, and since there are not many genes on the Y chromosome, the researcher includes housekeeping genes in the set of negative controls as well. Now, most of the control genes will be housekeeping genes and unaffected by gender. Thus, the $\alpha_{\star j_{c}}$ will not be representative of the $\alpha_{\star j_{\bar{c}}}$ of the genes on the X chromosome. RUV-4 may fail to properly adjust for gender. On the other hand, as long as $K$ is chosen large enough, gender should find its way into RUV-2's estimate of $W$, and RUV-2 may succeed in adjusting for gender.

Of course, with RUV-2, a relatively large $K$ may lead to problems of its own. In practice, the best option may sometimes be a hybrid of RUV-2 and RUV-4. For example, the researcher might choose to perform factor analysis on just the genes of the Y chromosome and keep only the first few factors. Assuming that gender is captured in these first few factors, the researcher might then choose to include these factors as covariates in RUV-4. Although these factors are estimated from negative controls (specifically, Y-chromosome genes), they could be incorporated into RUV-4 in exactly the same way known covariates are incorporated into RUV-4. In other words, the $W$ from RUV-2 (with Y-chromosome genes as controls) would now play the role of $Z$ in RUV-4 (with housekeeping genes as controls).

Of course, RUV-2 is not the only other method with which RUV-4 shares an interesting connection. As noted in the introduction, RUV-4 is of theoretical interest precisely because it shares similarities both with methods such as SVA and LEAPP, in which unwanted factors are estimated from the data and then included in the design matrix of a regression model, and with methods such as ICE and LMM-EH, in which unwanted variation is modeled as part of a complicated error term.

Consider first a comparison of RUV-4, SVA, and LEAPP. All model unwanted variation as arising from unobserved latent variables (our $W$ ), and assume that the number of latent variables (our $k$ ) is less than the number of samples (our $m$ ). Each of these methods requires an estimate of $k$. We estimate $k$ using the method of Section 3.6.6, while both SVA and LEAPP estimate $k$ using the method of Buja and Eyuboglu (1992). Each of the methods allows every gene to have its own variance (our $\sigma_{j}^{2}$ ), and estimates these variances in the "standard" way (from the residuals). Where these methods differ is in the exact method by which they estimate the latent factors. Even here, however, there are similarities - each of the methods begins by projecting away the factor of interest (with LEAPP, this is formulated as a rotation) in order to make sure that the factor of interest is not accidentally picked up with the unwanted factors. After this first step, though, the methods differ. RUV-4 relies on control genes to estimate $b_{W X}$. LEAPP proceeds somewhat similarly, and also estimates $b_{W X}$ as an intermediate step. Instead of relying on control genes, however, LEAPP assumes that $\beta$ is sparse, and then applies the outlier-detection algorithm $\Theta$-IPOD (She and Owen, 2011). SVA attempts to isolate genes that are primarily influenced by the unwanted factors but not influenced by the factor of interest, and then proceeds to estimate the unwanted factors by focusing the factor analysis on just those genes.

Consider now a comparison of RUV-inv (which is simply RUV-4 with $K=m-p-q$ ) and the mixed model methods ICE and LMM-EH. All model the unwanted variation as part of a random error term with a complicated covariance structure. In each of these methods, the covariance matrix is assumed to be of the form $\tau_{j}^{2} \Sigma+\sigma_{j}^{2} I$, where $\Sigma$ is the same for all genes. For the purposes of estimating $\beta$, RUV-inv effectively assumes that $\tau_{j}^{2}$ and $\sigma_{j}^{2}$ are constant across genes (see Section 3.7.4 and the discussion in Section A.3), but ICE and LMM-EH allow $\tau_{j}^{2}$ and $\sigma_{j}^{2}$ to vary by gene. For the purposes of estimating $\operatorname{Var}(\hat{\beta})$, however, all three methods allow $\sigma_{j}^{2}$ to vary by gene. The real difference between the methods is in the way the model is fit. Both ICE and LMM-EH fit all of the parameters of the model simultaneously using maximum likelihood methods. With RUV-inv, however, the covariance matrix is estimated using the control genes, $\beta$ is estimated using GLS, and $\sigma_{j}^{2}$ is estimated using the inverse method. It is the inverse method that is arguably the most
important difference between RUV-inv and other mixed model methods.
The inverse method for estimating variances is quite different from the methods that ICE and LMM-EH use to estimate variances. Indeed, the inverse method is unlike any other method of which we are aware.

Some readers may find the inverse method reminiscent of randomization tests. Both randomization tests and the inverse method make use of "random factors of interest." We too see similarities, and we have found the analogy with randomization tests to be helpful in developing intuition for what the inverse method is doing. Of course, there are also serious differences, perhaps the most obvious of which is that randomization tests are generally used with non-parametric models, whereas the inverse method is used in the context of a parametric model.

On an intuitive level, the inverse method may perhaps be best understood as a hybrid between traditional randomization tests and traditional parametric methods. This hybrid loses some of the nicer conceptual properties of randomization tests, but retains some of the practical benefits. The $p$-values produced by randomization tests (properly applied) have a very clear, believable interpretation. The $p$-values produced by the inverse method do not; inverse method $p$-values are computed using artificial modeling assumptions. On the other hand, like randomization tests, the inverse method does appear to maintain fairly good control of the type-1 error rate.

We conclude this paper with some suggestions for future research. One direction for improvement would be to allow $\sigma^{2}$ to vary not just by gene, but by sample. This would have immediate applications when combining data from different microarray platforms (e.g. Affymetrix arrays and Agilent arrays); the variance of the measured expression level of a gene can be quite different from one platform to another. By allowing $\sigma^{2}$ to vary from one batch to another, it may be possible to achieve an increase in power.

The method of empirical variances presents a second possibility for future improvements. Our development of the method of empirical variances in this paper has been mainly proof of principle. It seems very likely that improvements could be made. For example, other methods of non-linear regression may out-perform the minimum lower sets algorithm. Moreover, our implementation of the method of empirical variances relies on the assumption that $\beta$ is sparse, and ignoring outliers. Instead of assuming sparsity and ignoring outliers, however, it may be better to simply limit the non-linear regression to control genes. We did not pursue this approach because the function fit by the minimum lower sets algorithm is very flexible, and some of our datasets contained only a few hundred negative controls. The estimated regression function would be far too noisy. This problem could be solved, however, by either increasing the number of controls (e.g. empirical controls), or replacing the minimum lower sets algorithm with a less flexible alternative.

Additional possibilities for future research lay in the estimation of $k$. Our method for estimating $k$ relies on comparing the scale of the variation seen in $\hat{\beta}_{c}$ to the scale of the variation seen in $\hat{\alpha}_{c}$. Thus, since $\hat{\beta}$ is a function of $X$, our estimate of $k$ is also a function of $X$. However, factor analysis has many applications outside the removal of unwanted variation in differential expression analyses, and in many applications of factor analysis there is no factor of interest to play the role of our $X$. However, there may still be a need to know the number of factors. In such situations, a researcher could simply choose many $X^{\star}$ at random and produce many different estimates of $k$. A final estimate of $k$ could then be produced, for example, by taking the median. Note, moreover, that with a random $X^{\star}$, we might wish to regard every gene (or more generally, "feature") as a control gene, on the grounds that no gene should be "truly" differentially expressed with respect to a random $X^{\star}$. Thus, if we estimate $k$ via random $X^{\star}$, it is not even necessary to have any negative controls. Such a method may therefore present a novel and widely applicable solution to the number-of-factors problem.

Finally, we would like to reiterate our belief that significant advances may be made by fully exploiting the functional approach. In particular, the possibility of incorporating "outside" information, such as a gene's GC content, seems to hold great promise.

## A Miscellaneous Derivations and Discussions

## A. 1 The Parameterization of $\hat{W}_{0}$ Does Not Matter

Recall that the parameterization of $\hat{W}$ does not matter. If $\tilde{W}$ is a reparameterization of $\hat{W}$ in the sense that $\mathfrak{R}(\tilde{W})=\mathfrak{R}(\hat{W})$, then the resulting $\hat{\beta}$ will be the same whether we use $\tilde{W}$ or $\hat{W}$. The point of this section is to show that the parameterization of $\hat{W}_{0}$ does not matter either. More formally, we wish to show that if $\mathfrak{R}\left(\tilde{W}_{0}\right)=\mathfrak{R}\left(\hat{W}_{0}\right)$ and if $\tilde{W}$ and $\hat{W}$ are the corresponding estimates of $W$ computed using Step 3 of RUV-4, then $\mathfrak{R}(\tilde{W})=\mathfrak{R}(\hat{W})$.

Let $\tilde{W}_{0}=\hat{W}_{0} Q$ where $Q$ is any $k \times k$ invertible matrix. Then

$$
\begin{align*}
\tilde{\alpha}_{c} & \equiv\left[\left(\hat{W}_{0} Q\right)^{\prime} \hat{W}_{0} Q\right]^{-1} Q^{\prime} \hat{W}_{0}^{\prime} Y_{c}  \tag{254}\\
& =Q^{-1}\left(\hat{W}_{0}^{\prime} \hat{W}_{0}\right)^{-1} \hat{W}_{0}^{\prime} Y_{c}  \tag{255}\\
& =Q^{-1} \hat{\alpha}_{c} \tag{256}
\end{align*}
$$

and

$$
\begin{align*}
\tilde{b}_{W X} & \equiv b_{Y_{c} X} \tilde{\alpha}_{c}^{\prime}\left(\tilde{\alpha}_{c} \tilde{\alpha}_{c}^{\prime}\right)^{-1}  \tag{257}\\
& =b_{Y_{c} X} \hat{\alpha}_{c}^{\prime}\left(Q^{-1}\right)^{\prime}\left[Q^{-1} \hat{\alpha}_{c} \hat{\alpha}_{c}^{\prime}\left(Q^{-1}\right)^{\prime}\right]^{-1}  \tag{258}\\
& =b_{Y_{c} X} \hat{\alpha}_{c}^{\prime}\left(\hat{\alpha}_{c} \hat{\alpha}_{c}^{\prime}\right)^{-1} Q  \tag{259}\\
& =\hat{b}_{W X} Q \tag{260}
\end{align*}
$$

so

$$
\begin{align*}
\tilde{W} & \equiv \tilde{W}_{0}+X \tilde{b}_{W X}  \tag{261}\\
& =\hat{W}_{0} Q+X \hat{b}_{W X} Q  \tag{262}\\
& =\hat{W} Q . \tag{263}
\end{align*}
$$

## A. 2 Reformulation of the OLS Variance

Assume that $X$ has unit length and that the columns of $W_{0}$ are orthogonal and have unit length. Let $\hat{\beta}^{(\mathrm{OLS})}$ be the OLS estimate of $\beta$ (ignore for the moment that $W$ is unknown). The variance of $\hat{\beta}_{j}^{(\mathrm{OLS})}$ is the $(1,1)$ entry of the matrix $\sigma_{j}^{2}\left[(X \mid W)^{\prime}(X \mid W)\right]^{-1}$. The goal of this section is to show that this is equal to $\sigma_{j}^{2}\left(1+b_{W X} b_{W X}^{\prime}\right)$.

[^5]Begin with the observation that

$$
\left[(X \mid W)^{\prime}(X \mid W)\right]^{-1}=\left(\begin{array}{cc}
X^{\prime} X & X^{\prime} W  \tag{264}\\
W^{\prime} X & W^{\prime} W
\end{array}\right)^{-1}
$$

We can invert this matrix block-wise. The $(1,1)$ entry is equal to

$$
\left[X^{\prime} X-X^{\prime} W\left(W^{\prime} W\right)^{-1} W^{\prime} X\right]^{-1}
$$

Now, $X^{\prime} X=1, X^{\prime} W=b_{W X}, W^{\prime} X=b_{W X}^{\prime}$, and $W^{\prime} W=I+b_{W X}^{\prime} b_{W X}$, so

$$
\begin{align*}
\operatorname{Var}\left[\hat{\beta}_{j}^{(\mathrm{OLS})}\right] & =\sigma_{j}^{2}\left[1-b_{W X}\left(I+b_{W X}^{\prime} b_{W X}\right)^{-1} b_{W X}^{\prime}\right]^{-1}  \tag{265}\\
& =\sigma_{j}^{2}\left\{1-b_{W X}\left[I-b_{W X}^{\prime}\left(I+b_{W X} b_{W X}^{\prime}\right)^{-1} b_{W X}\right] b_{W X}^{\prime}\right\}^{-1}  \tag{266}\\
& =\sigma_{j}^{2}\left[1-b_{W X} b_{W X}^{\prime}+b_{W X} b_{W X}^{\prime}\left(1+b_{W X} b_{W X}^{\prime}\right)^{-1} b_{W X} b_{W X}^{\prime}\right]^{-1}  \tag{267}\\
& =\sigma_{j}^{2}\left[1-x+x(1+x)^{-1} x\right]^{-1}  \tag{268}\\
& =\sigma_{j}^{2}\left(\frac{1-x^{2}}{1+x}+\frac{x^{2}}{1+x}\right)^{-1}  \tag{269}\\
& =\sigma_{j}^{2}(1+x)  \tag{270}\\
& =\sigma_{j}^{2}\left(1+b_{W X} b_{W X}^{\prime}\right) \tag{271}
\end{align*}
$$

where $x \equiv b_{W X} b_{W X}^{\prime}$.

## A. 3 Estimating $\Sigma_{j}$ as $\frac{1}{n_{c}}\left(Y_{c} Y_{c}^{\prime}\right)+\left(\hat{\sigma}_{j}^{2}-\dot{\sigma}_{c}^{2}\right) I$

In Section 3.7.4 we made the observation that

$$
\begin{align*}
\mathbb{E}\left[\frac{1}{n_{c}}\left(Y_{c} Y_{c}^{\prime}\right)\right] & =\Sigma+\bar{\sigma}_{c}^{2} I  \tag{272}\\
& \neq \Sigma+\bar{\sigma}_{j}^{2} I  \tag{273}\\
& =\Sigma_{j} . \tag{274}
\end{align*}
$$

$\frac{1}{n_{c}}\left(Y_{c} Y_{c}^{\prime}\right)$ is a biased estimator of $\Sigma_{j}$. In this section we will consider alternative estimators of $\Sigma_{j}$. Specifically, we will consider estimators of the form

$$
\begin{equation*}
\hat{\Sigma}_{j}=\frac{1}{n_{c}} Y_{c} Y_{c}^{\prime}+\lambda I . \tag{275}
\end{equation*}
$$

For a given estimator $\hat{\Sigma}_{j}$ it can be shown that

$$
\begin{equation*}
\operatorname{Var}\left[\hat{\beta}_{j} \mid \hat{\Sigma}_{j}\right]=\left(X^{\prime} \hat{\Sigma}_{j}^{-1} X\right)^{-1} X^{\prime} \hat{\Sigma}_{j}^{-1} \Sigma_{j} \hat{\Sigma}_{j}^{-1} X\left(X^{\prime} \hat{\Sigma}_{j}^{-1} X\right)^{-1} \tag{276}
\end{equation*}
$$

For our purposes, a good estimator of $\hat{\Sigma}_{j}$ is one such that

$$
\begin{equation*}
\mathbb{E}\left\{\operatorname{Var}\left[\hat{\beta}_{j} \mid \hat{\Sigma}_{j}\right]\right\} \tag{277}
\end{equation*}
$$

is small.

Let

$$
\begin{align*}
\hat{\Sigma}_{j}(\lambda) & \equiv \frac{1}{n_{c}} Y_{c} Y_{c}^{\prime}+\lambda I  \tag{278}\\
\hat{\beta}_{j}\left(\hat{\Sigma}_{j}\right) & \equiv\left(X^{\prime} \hat{\Sigma}_{j}^{-1} X\right)^{-1} X^{\prime} \hat{\Sigma}_{j}^{-1} Y_{\star j}  \tag{279}\\
\lambda^{*} & \equiv \underset{\lambda}{\operatorname{argmin} \operatorname{Var}}\left[\hat{\beta}_{j}\left(\hat{\Sigma}_{j}(\lambda)\right) \mid \hat{\Sigma}_{j}(\lambda)\right] . \tag{280}
\end{align*}
$$

We will consider 5 "estimators."

$$
\begin{align*}
\hat{\Sigma}_{j}^{(1)} & =\Sigma+\sigma_{j}^{2} I  \tag{281}\\
\hat{\Sigma}_{j}^{(2)} & =\frac{1}{n_{c}} Y_{c} Y_{c}^{\prime}+\lambda^{*} I  \tag{282}\\
\hat{\Sigma}_{j}^{(3)} & =\frac{1}{n_{c}} Y_{c} Y_{c}^{\prime}+\left(\sigma_{j}^{2}-\bar{\sigma}_{c}^{2}\right) I  \tag{283}\\
\hat{\Sigma}_{j}^{(4)} & =\frac{1}{n_{c}} Y_{c} Y_{c}^{\prime}+0.2\left(\sigma_{j}^{2}-\bar{\sigma}_{c}^{2}\right) I  \tag{284}\\
\hat{\Sigma}_{j}^{(5)} & =\frac{1}{n_{c}} Y_{c} Y_{c}^{\prime} \tag{285}
\end{align*}
$$

Note that only $\hat{\Sigma}_{j}^{(5)}$ is a real estimator that can be computed from data. $\hat{\Sigma}_{j}^{(1)}=\Sigma_{j}$ is the true parameter. $\hat{\Sigma}_{j}^{(2)}$ is the optimal estimator of the form $\frac{1}{n_{c}} Y_{c} Y_{c}^{\prime}+\lambda I$. To compute it requires knowledge of $\Sigma_{j}$. $\hat{\Sigma}_{j}^{(3)}$ is an idealization of the estimator briefly mentioned in Section 3.7.4. Here we have substituted the parameter $\left(\sigma_{j}^{2}-\bar{\sigma}_{c}^{2}\right)$ for the estimate $\left(\hat{\sigma}_{j}^{2}-\dot{\sigma}_{c}^{2}\right) . \hat{\Sigma}_{j}^{(4)}$ is a modified version of $\hat{\Sigma}_{j}^{(3)}$. The choice of 0.2 is arbitrary.

We want to compare the performance of the $\hat{\Sigma}_{j}^{(i)}$. This is difficult to accomplish analytically. Instead we will use simulations. Define

$$
\begin{equation*}
\hat{\beta}_{j}^{(i)} \equiv \hat{\beta}_{j}\left(\hat{\Sigma}_{j}^{(i)}\right) \tag{286}
\end{equation*}
$$

Let

$$
\begin{equation*}
v_{i}\left(\sigma_{j}^{2}\right) \equiv \mathbb{E}\left\{\operatorname{Var}\left[\hat{\beta}_{j}\left(\hat{\Sigma}_{j}^{(i)}\right) \mid \hat{\Sigma}_{j}^{(i)}\right]\right\} \tag{287}
\end{equation*}
$$

denote the expected variance when $\sigma_{j}^{2}$ is the true parameter. Note that $v_{i}$ should be indexed by $j$ and should also be a function of $\Sigma, \sigma_{c}^{2}$ and $X$ but we suppress this in the notation. We consider three quantities of interest: $\sqrt{v_{i}\left(\sigma_{j}^{2}\right)}, \sqrt{v_{i}\left(\sigma_{j}^{2}\right) / v_{1}\left(\sigma_{j}^{2}\right)}$, and $\sqrt{v_{i}\left(\sigma_{j}^{2}\right) / v_{2}\left(\sigma_{j}^{2}\right)}$. The first is the RMSE of $\hat{\beta}_{j}\left(\hat{\Sigma}_{j}^{(i)}\right)$. The second is the RMSE of $\hat{\beta}_{j}\left(\hat{\Sigma}_{j}^{(i)}\right)$ as a fraction of the RMSE of the ideal estimator $\hat{\beta}_{j}(\Sigma)$. The third is the RMSE of $\hat{\beta}_{j}\left(\hat{\Sigma}_{j}^{(i)}\right)$ as a fraction of the RMSE of the "best possible" estimator $\hat{\Sigma}_{j}^{(2)}$. Of course, in practice, $\hat{\Sigma}_{j}^{(2)}$ is not actually a possible estimator. Simulation results are given in Figure 14.

A quick glance at Figure 14 reveals that the performance does vary from one estimator to the next, but not always by very much. The one exception is $\hat{\beta}_{j}^{(3)}$, which performs horribly when $\sigma_{j}^{2} / \bar{\sigma}_{c}^{2}<1$. Therefore, even if unbiased estimates $\hat{\sigma}_{j}^{2}$ of $\sigma_{j}^{2}$ and $\dot{\sigma}_{c}^{2}$ of $\bar{\sigma}_{c}^{2}$ are available, and $\frac{1}{n_{c}}\left(Y_{c} Y_{c}^{\prime}\right)+\left(\hat{\sigma}_{j}^{2}-\dot{\sigma}_{c}^{2}\right) I$ is therefore an unbiased estimator of $\Sigma_{j}$, this estimator should not be used! This result is perhaps to be anticipated. The smallest eigenvalue of $\frac{1}{n_{c}}\left(Y_{c} Y_{c}^{\prime}\right)$ will often be considerably smaller than $\sigma_{j}^{2}$. As a result $\frac{1}{n_{c}}\left(Y_{c} Y_{c}^{\prime}\right)+\left(\sigma_{j}^{2}-\bar{\sigma}_{c}^{2}\right) I$ may have tiny - or even negative - eigenvalues.
$\hat{\beta}_{j}^{(4)}$ improves on $\hat{\beta}_{j}^{(3)}$ by "shrinking" the ridge-adjustment term $\left(\sigma_{j}^{2}-\bar{\sigma}_{c}^{2}\right) I$. Indeed, $\hat{\beta}_{j}^{(4)}$ performs quite well. However, the shrinkage factor of 0.2 is arbitrary; we chose 0.2 simply because it gave good results. Implementing this "shrunken ridge adjustment" strategy in practice would require a method for choosing a

Figure 14: Plots of $\sqrt{v_{i}\left(\sigma_{j}^{2}\right)}, \sqrt{v_{i}\left(\sigma_{j}^{2}\right) / v_{1}\left(\sigma_{j}^{2}\right)}$, and $\sqrt{v_{i}\left(\sigma_{j}^{2}\right) / v_{2}\left(\sigma_{j}^{2}\right)}$ as $\sigma_{j}^{2}$ is varied from $0.1 \bar{\sigma}_{c}^{2}$ to $10 \bar{\sigma}_{c}^{2}$. The vertical axis is the quantity of interest, e.g. $\sqrt{v_{i}\left(\sigma_{j}^{2}\right)}$, and the horizontal axis is $\log _{10}\left(\sigma_{j}^{2} / \bar{\sigma}_{c}^{2}\right)$. The coloring scheme is as follows: $i=1$, thick black line; $i=2$, thin black line; $i=3$, red; $i=4$, violet; $i=5$, blue. The simulation parameters are the same as those of the simulations presented in Section 4. $n_{c}=1000$. We show the results for three separate simulations ("Lightly Correlated," "Moderately Correlated," "Highly Correlated."). $i=3$ is omitted from the left column because it behaves too erratically.
good shrinkage factor. This would presumably depend on $\Sigma, n_{c}$, the distribution of $\sigma^{2}$, etc. In practice we would also need to account for the fact that $\sigma_{j}^{2}$ and $\bar{\sigma}_{c}^{2}$ are not known, but estimated.

Figure 14 suggests an alternative strategy. Set

$$
\hat{\beta}_{j}^{(6)} \equiv \begin{cases}\hat{\beta}_{j}^{(5)} & \text { if } \sigma_{j}^{2}<\bar{\sigma}_{c}^{2}  \tag{288}\\ \hat{\beta}_{j}^{(3)} & \text { if } \sigma_{j}^{2} \geq \bar{\sigma}_{c}^{2}\end{cases}
$$

In the simulations of Figure 14, $\hat{\beta}_{j}^{(6)}$ performs quite well. We have not investigated whether this strategy works well more generally. In practice, of course, we would need to replace $\sigma_{j}^{2}$ with $\hat{\sigma}_{j}^{2}$ and $\bar{\sigma}_{c}^{2}$ with $\dot{\sigma}_{c}^{2}$. If these estimates are very noisy, $\hat{\beta}_{j}^{(6)}$ may no longer perform well.

Finally, we note that in the big picture, the performance of $\hat{\beta}_{j}^{(5)}$ is adequate. In the lightly and moderately correlated examples, the RMSE of $\hat{\beta}_{j}^{(5)}$ is only larger than the "best possible" RMSE by about $5 \%$. In the figures and tables of Section B we see that a $5-10 \%$ increase in the RMSE of $\hat{\beta}$ is relatively minor compared to the choice of $K$, the choice of method, the choice of controls, etc. Perhaps more importantly, in Section 4.2 of the main text we argue that the primary determinant of the discriminative power is the performance of $\hat{\sigma}^{2}$, not the performance of $\hat{\beta}$. It is for these reasons that we feel that $\hat{\beta}_{j}^{(5)}$ is generally adequate.

[^1]:    ${ }^{1}$ Strictly speaking this is not true, since the regression line and the SD line as defined in Freedman et al. (2007) both pass through the point of averages. We, however, force our lines to pass through the origin.

[^2]:    ${ }^{2}$ The obvious question now is how to choose $K_{0}$. We do not explore this question in detail, but note that one simple strategy is to simply let $K_{0}$ vary with $i$ and set $K_{0}=i$.

[^3]:    ${ }^{3}$ Note that we do not include comparisons with LMM-EH (Listgarten et al., 2010), since no R package is currently available. However, we suspect that the performance of LMM-EH would be similar to that of ICE, although LMM-EH may exhibit somewhat better control of the type 1 error rate. Note Figure 2 of Listgarten et al. (2010); the ROC curve of LMM-EH and ICE are nearly identical.

[^4]:    ${ }^{4}$ It is worth noting that in the course of our analyses we have been unable to produce any convincing evidence that there are any autosomal genes that are differentially expressed between the brains of men and women. To be sure, in each of the datasets we examine, there are a few autosomal genes with small FDR-adjusted $p$-values. However, none of these genes are consistently "significant" across multiple datasets.
